Pythagoras (580-489 B. C.) founded the school of philosophers in Crotona, where he was driven from Samos by the tyranny of Polycrates. He was the first to suspect the functions of the brain, and devised a system of numbers in diagnosing diseases, namely, unity as the symbol of God and perfection, and twelve for the universe. This he applied to abnormal conditions for comparison. Then came Plato and Aristotle, who taught four principles or qualities—heat, dry, moist, and cold, and formulated them as follows: Heat plus dry equals fire; cold plus dry equals earth; heat plus moist equals air; cold plus moist equals water. From these arose the humoral pathology of Galen, the basis of which was that the body was made up of four humors: blood, phlegm, yellow bile and black bile, i. e., heat and moist equals blood; cold and moist equals phlegm; heat and dry equals yellow bile; cold and dry equals black bile.

THE CLASSICAL PERIOD.

The classical period began with Hippocrates, 460 B. C., and lasted to the fall of the Western Empire in 476 A. D. Hippocrates was born on the Island of Cos. He was one of the family of the

Æsclepiadæ and the contemporary of Socrates and Plato. He was educated by his father Herocles and by Hiradicus. He was the real father of medicine. His methods were similar to those of the modern practitioner, and his description of diseases is still of value. He was the first physician to commit his teachings to writing, and therefore was the father of medical literature. His great achievements were the writing of the Hippocratic oath and the description, known as the Hippocratic facies, of one approaching death. He wrote on prognosis, epidemics, diet in acute disease, wounds of the head, air, water and place. He also wrote medical aphorisms and described tuberculosis, puerperal convulsions, mumps, and epilepsy. He observed the pulse, temperature, respiration, facies, sputum, pain, and movements when predicting the outcome of a case. His great merit lay in the fact that he believed in giving nature her chance, and dispensed with drugs as far as possible. He relied chiefly on fresh air, good diet, purgation, tisanes of barley, wine, massage, and hydrotherapy. His clinical histories were the only ones for 1700 years. His other great achievements were: First, the separation of medicine from theurgy and philosophy; second, the making of a connected and symmetrical science from a mass of disconnected teachings; third, the exercise of a beneficial, moral influence upon the practitioner of his time. After Hippocrates there were no great medical teachers until Aristotle, whose contributions to medicine were studies of comparative anatomy, embryology, and formal logic. He named the aorta and probably had an accurate idea of the function of the blood. The empirical school of medicine flourishing then rejected all etiology and anatomy and laid weight on the empirical tripod: 1, History of the particular case; 2, its analogy to similar cases, and 3, its accidental surroundings.

Roman Medicine.—Before Galen, Roman medicine was a riot of theories. Thus, Asclepiades of Bithyma, 124 B. C., believed in a relaxed or constricted state of the body, or solidism, as a cause of disease. Celsus wrote on malarial fever, gout, and insanity. Dioscorides is said to have originated the *materia medica* and Arctacus ranked next to Hippocrates as a clinician and writer. His accounts of pneumonia, diabetes, lockjaw, elephantiasis, and diphtheria are classical. Galen (131-201) was one of the greatest physicians in ancient medicine. He believed that disease was abnormal and that health might be conserved by the upbuilding of the body. He believed in the four humors mentioned above, and was a great user of drugs. He was an anatomist and an experimental physiologist, and described the infectious character of tuberculosis, treating it with fresh air, change of climate, and good diet. He also described and recognized the distinction between pleurisy and pneumonia, and described aneurysm. But he also believed in the efficiency of amulets, the doctrine of vitalism, i. e., that the blood received natural spirits from the liver, vital spirits from the heart, animal spirits from the brain, and that the blood poured from the right heart into the left through invisible pores; that pus served a good purpose in wounds. He was

the originator of the famous anodyne necklace which was so long used in England. These errors were hardly questioned for about 1500 years. He was also a voluminous writer on medical and philosophical subjects; very interesting were his writings on Anatomical Administrations and the Use of the Parts of the Human Body. He was also a practical dissector of lower animals. Quackery was rampant in Rome because the Roman citizens were not encouraged to study medicine. Many slaves became doctors. The *Servi Medici* were doctors who were prisoners but had to serve in their professional capacity.

MEDIEVAL MEDICINE.

There was but little progress made in medicine during the middle ages, as Galen seemed to have said the last words on the subject, and most of the writers compiled from his works. The Byzantine Empire produced four medical writers, Aribasins (326-403), who wrote an encyclopedia of over seventy volumes; Ætius of Amida (sixth century), wrote well of disease of the eye, nose, mouth, and teeth; Alexander of Tralles (526-605), wrote on worms and vermifuges, and Paul Ægineta wrote an epitome of medicine in seven books.

Arabian Medicine.—Rhazes (860-932), a physician of the Eastern Caliphate, gave the first authentic account of smallpox and measles. Avicenna (980-1037), wrote the *Canon*, a system of medicine in which theorizing took the place of experimenting. The most renowned physicians of the Western Caliphate were Avenzaar, who described the itch mite and was the first parasitologist, and Moses ben Maimon, who wrote a book on hygiene. They described the heart as the prince of the body; the lungs as the fan of the heart; liver as its guard and habitat of the soul; pit of the stomach as the seat of pleasure; and gallbladder the seat of courage. Their hospitals were excellent. The Alman-sur Hospital at Cairo perhaps surpassed many present day institutions in its humanitarian practices.

Jewish Medicine.—At this time Jewish medicine was just like Arabian. The ancient Hebrews were banished in 1412 from the Western Caliphate, and were not allowed to study medicine at European universities until the time of the French revolution. In spite of that, much of the progress from hypothetical to scientific medicine was due to this race.

The famous medical school at Salerno arose from a little health resort. The school lasted several centuries, after Robert, son of William the Conqueror, was treated successfully for a wound in the head, in 1101, and was abolished by Napoleon in 1811. The ceremonies used for conferring medical degrees at Salerno are copied even today. The degree of doctor of medicine was conferred upon the graduates of Salerno by Gilles de Corbeil in the twelfth century.

Other great schools were at Palermo, Naples and Montpellier. Toward the close of the medieval period medical science began to free itself from the doctrines of Galen, and received the benefit of some independent thinking. The leader of the intellectual revolution was Henri de Mondeville

(1260-1320), who advocated clean surgery, and in a measure was the first asepsist. In 1140 Roger of Sicily formulated some admirable hygienic regulations. In the middle of the fourteenth century a series of epidemics, such as leprosy, St. Anthony's fire, scurvy, influenza, and bubonic plague, ravaged Europe. It is estimated that about one quarter of the earth's inhabitants or over 60,000,000 people perished in a period of two years. Syphilis appeared in Europe in 1495 at the siege of Naples.

PHILOSOPHICAL MEDICINE.

Superstition still reigned during this period, and what is known as signatures was practised, i. e., using drugs that have a resemblance to a disease to treat it; for instance, yellow plants for jaundice; red ones for anemia; trefoil for heart disease; thistle for a stitch in the side; walnuts for diseases of the head, etc. Paracelsus (1493-1541), whose real name was Van Hohenheim, was the earliest prominent physician of this period. He boldly attacked Galen, Avicenna and others, publicly burned their writings and prepared the way for modern medicine. He was the only asepsist between Mondeville and Lister. He wrote also on occupational diseases, cretinism and goitre, and lectured in his native tongue, a startling innovation not repeated for over three hundred years. Thomas Linacre (1460-1524) established the medical department of the universities of Oxford and Cambridge. Due to his influence Henry VIII made it obligatory for candidates to pass examinations in medicine to secure a degree from one of the universities. Andreas Vesalius (1514-1564) was the first great anatomist, and published *De Fabrica Humana Corporis*, the first anatomy worth its name. He ridiculed Galen's description of the heart, taught artificial respiration, and held that the brains of lower animals functionated the same as man's. Two of his pupils became famous: Fallopius (1523-1562), who named the Fallopian tube, and Eustachius (1524-1603), who named the Eustachian canal. Vesalius through anatomical drawings hinted at the circulation of the blood, and Servetus (1509-1553) also suspected it.

During the sixteenth century much progress was made in medicine. Andreas Cesalpino (1524-1603), an Italian, formulated a theory closely approximating the true circulation of the blood, later proved by Harvey. The famous Bedlam Asylum was started in 1547. Leprosy, cholera, and sweating sickness practically disappeared from Europe by the middle of this century, syphilis and bubonic plague remaining.

The greatest physician of the seventeenth century was Harvey (1578-1657), who discovered the true circulation of the blood. His other great contribution to medicine was his theory of generation that overthrew the ancient assumption that life was derived from a sort of putrefaction. Although he stated that the heart was a muscular force pump, he did not know its source of power, and attributed it to innate heat, celestial in nature and identical with the essence of stars. Later, Malpighi (1628-1694), with the aid of the microscope, discovered how the terminations of the arterial and venous blood vessels empty into each other, and he supplied

the last link to Harvey's chain. Thomas Sydenham (1624-1689) and John Garut, who published the first book on vital statistics, were great physicians of that day. There was still much superstition in medicine and materia medica, which had reference to worms, dried vipers, fox's lungs, powder of jewels, moss from the skull of a murdered man, crab's eyes, oil of bricks, etc. Charles II gave \$50,000 for the formula of Goddard drops recommended by Sydenham, made from raw silk.

The eighteenth century was filled with systems and theories. George E. Stahl (1660-1734) wrote on the liver and tear duct and on a theory of an imaginary component of the body he called phlogiston, which he considered necessary to all vital processes. Herman Boerhaave (1668-1738), the greatest physician of the eighteenth century, was the first to prove that smallpox was contagious and that pleurisy was confined to the pleura. Morgagni (1682-1771) when seventy-nine years old published a work which proved to be the basis of modern pathology. Sir John Floyer (1649-1734) timed the pulse rate with a one minute watch. Dr. G. Martini (1702-1741), a Scotchman, discovered the clinical thermometer. Dr. Van Haller was noted for his surgical treatment of aneurysm. Dr. Auenbrugger (1722-1809) introduced percussion of the chest as a means of diagnosis. Toward the end of the eighteenth century came Dr. Jenner's great discovery of vaccination, a preventive against smallpox. The hospitals of the eighteenth century were kept so filthy that operation practically meant death. There was really no clean surgery until Lister's time, and no humane treatment for the insane until William Turke, in 1793, started the Yorke treatment. The charlatans of the eighteenth century were numerous and picturesque. The most notorious were Sir William Reed, known as Spot Ward, and Joanna Stevens.

About 1800 the Royal College of Surgeons was incorporated, connected with some of the hospitals in London, as Guy's, St. Bartholomew, St. Thomas, and St. George at that time were medical schools, in which the teachers were the attending physicians and surgeons of the respective hospitals. Scotland antedates England in the matter of medical education. The medical school of St. Andrews was founded in 1411, and that of the University of Edinburgh in 1582.

The first half of the nineteenth century was largely a continuation of the theorizing of the eighteenth century; the chief progress was made by the French physician Francois Victor Broussais (1772-1838), whose theory was that disease was caused by too much heat concentration on one particular organ. He bled his patients profusely, so that France in 1883 imported over forty-three million leeches. Soon after Lewis proved through statistics that leeches were harmful, and this practice was stopped. He was the founder of medical statistics. Parkinson (1755-1824) reported the first case of appendicitis in England, and gave his name to paralysis agitans. Laennec (1781-1826) invented the stethoscope and in 1823 wrote a textbook on thoracic diseases. Pinel (1745-1826) risked his life

for the insane, who up to this time were treated worse than criminals. Pelletier and Conventon discovered quinine in 1820, and thereby malaria was cured. The greatest English clinician of that day was Dr. Richard Bright (1789-1858), who distinguished between the various forms of kidney lesions and classified kidney diseases, a classification which is used even today by such great clinicians and surgeons as the Mayos. Kidney disease is commonly known as Bright's disease ever since his writings on this subject. Thomas Addison (1793-1860) wrote a monograph on the local and constitutional effects of disease of the suprarenal capsules, and opened the field for the study of the ductless glands and their internal secretions. Semmelweis (1818-1865) and Oliver Wendell Holmes (1809-1894) discovered the true cause of puerperal fever. S. C. F. Hahnemann (1755-1843) founded a new cult called homeopathy, on theories akin (intellectually) to the doctrine of signatures, the first tenet being that "like cures like," a generalization dating back to 650 B. C. The second tenet was that infinitesimal doses should be given which were supposed when shaken violently to develop mysterious powers—probably to correct a defect in those days of overdosing patients with drugs. Hahnemann claimed divine inspiration. It had an immense vogue for a number of years. Homeopathy of today has departed widely from the original teachings of the founder. John Hunter, a British surgeon and physiologist, in 1760 wrote on the blood, inflammation, and gunshot wounds. His museum contains wonderful anatomical and surgical specimens now with the Royal College of Surgeons. William Hunter (1718-1783), an older brother, wrote an *Anatomical Description of the Human Gravid Uterus and Its Contents*. He was an obstetrician.

SCIENTIFIC MEDICINE.

Scientific medicine began about the middle of the nineteenth century. It was about this time, 1845, that Darwin and Wallace promulgated their views on evolution. Magendie (1783-1855) was a pioneer in experimental physiology; Schleiden (1804-1881) and Schumann (1810-1882) developed the knowledge of cell growth. Rudolph Virchow (1821-1859) began in 1847 the publication of *Archiv für pathologische Anatomie*, now *Virchow's Archives*. His first number took a stand against improved hypothesis and the infallibility of any one man, thus striking the keynote of modern medicine. In 1858 he published a book on cellular pathology, with which began the European period of modern medicine. His famous epitaph was *omnis cellule e cellula*; that is, where there is growth of cells there must have been cells preceding them. Henle (1809-1885) was one of the greatest anatomists of all time. In 1840 he published his observations which were the nucleus of the germ theory of disease. Louis Pasteur (1822-1895), who was originally a chemist, was the father of bacteriology. The whole field of preventive inoculations is due directly to him, and he is credited with discovering the preventive treatment of hydrophobia. Emil von Behring in 1894 discovered diphtheria antitoxin. Asepsis and antisepsis in surgery was

the epoch making work of Lister (1827-1912), and due directly to Pasteur's teachings. Claude Bernard (1813-1878), the leading physiologist of the century, discovered the glycogenic function of the liver, which proved that the body could build up or break down substances itself. Von Baers (1792-1876) discovered the mammalian ovum, and did for embryology what Cuvier did for anatomy—made it comparative. Von Friedreich in 1857 was the first to describe acute myelogenous leucemia. Friedlebens in 1858 in a monograph, *Die Physiologie der Thymusdrüse*, described the thymus gland perfectly. Hubner wrote on endarteritis in 1874. Cannon, Harvey, and Cushing of America, and Pavlov of Russia continued along lines laid down by Bernard Laveran in 1881, who discovered the malarial parasite. Robert Koch in 1882 discovered the tubercle bacillus and formulated the Koch postulates to prove a germ disease. Schaudinn in 1905 discovered the *Spirochæta pallida*; Wassermann, Neisser, and Bruck in 1906 discovered the serum diagnostic Wassermann test; Plaut in 1908 tested the spinal fluid for the Wassermann reaction. Ehrlich (1854-1919) did an immense amount of work on metabolism, and promulgated and theorized the side chain theory of disease. After a series of experiments he discovered, in 1909, salvarsan or 606 for the treatment of syphilis, and later on neosalvarsan. His pupil Abderhalden in 1877 studied metabolism and evolved the biochemical test for pregnancy. Swift, Ellis, and Byrnes in 1912 perfected salvarsanized serum and treated nervous syphilis by injecting salvarsan directly into the spinal canal. Quincke in 1891 described the technic of lumbar puncture; and cytodagnosis of the cerebrospinal fluid, as described by Ravaut, Siccard, Nageotti, and Widal, in 1901, was classical. In 1903 they described the albumin significance of the cerebrospinal fluid. Roux and Metchnikoff in 1903 experimented with the transmission of syphilis to apes. In 1904 Alzheimer wrote on the histopathology of brain syphilis. Noguchi and Moore found spirochetes in brain tissues of paresis in 1913, and Lange described the gold-sol test in 1913.

Anæsthesia.—Crawford W. Long, of Georgia, in 1842-43 used ether in several cases. Horace Wells, a dentist of Connecticut, in 1844 began the use of laughing gas or nitrous oxide, and communicated this to his friend, W. T. G. Morton, who later experimented with it and with the aid of J. C. Warren and H. J. Bigelow, made the discovery known to the medical profession. In 1831, Guthrie, Liebig, and Soubieran introduced chloroform, purified and named by Dumas in 1834, and used by Sir J. Young Simpson (1811-1870) in 1847 in obstetrics. Cocaine was first isolated by Niemann in Wohler's laboratory in 1858, but not used in medicine until 1884, when Carl Coller called attention to its advantage as a local anesthetic. The discovery of anesthesia revolutionized surgery, and as Weir Mitchell remarked, it was the death of pain. Hypodermic injection for the relief of pain was first administered and introduced to the profession by Francis Rynd, of Dublin, and Dr. Provaz in 1845-1852. The laryngoscope was first used by V. von Bruns in 1862.

Poiselli in 1828 introduced the first U tube mercurial manometer, and shortly afterward Ludwig devised the kymographion, which connected directly to an open artery, recording the pulse wave on a revolving cylinder. Dr. Marey in 1876 originated the first useful blood pressure apparatus or sphygmomanometer by which he could determine both the systolic and diastolic blood pressures and the pulse pressure. Riva-Rocci in 1896 devised the first sphygmomanometer with cuff arrangement as used at the present time, only the cuff was too narrow and gave rise to various modifications for greater accuracy and better results. This led to the discovery of the electrocardiograph, a great aid in the diagnosis of abnormal conditions of the heart.

Electrotherapy was first used in modern medicine by Duchenne. The x ray was discovered by Dr. William Conrad Röntgen in 1893. Mental medicine was in a chaotic state until Emil Kraepelin in 1856 brought order into its study. Sigmund Freud in 1895 promulgated a new psychology known as psychoanalysis. His two chief disciples, C. G. Jung and Alfred Adler, started schools of their own. Alfred Binet and Th. Simon in 1905 and 1908 devised tests for measuring the intellectual capacities of children. Goddard, Yerks, Fernald, and Healy did similar work in America. In 1856 Sir William H. Perkins obtained aniline dyes from coal tar products and marked the beginning of the manufacture of phenacetin, acetanilid, and similar drugs.

In 1910 R. G. Harrison demonstrated that nerve cells could be preserved and grown outside of the body. Then Alexis Carrel proceeded to preserve other tissues outside of the body, and even transplanted organs and limbs from man to man. He also did wonderful work of this kind during the world war, and where these astonishing feats will end it is indeed difficult to say. Dr. G. W. Crile elaborated the theory of anociassociation or blocking of harmful stimuli, and hence preventing shock during operations. He accomplishes this by administering local and general anesthesia together with psychological handling before operating. Sir William Osler (1839), Canadian by birth, was a good clinician and teacher whose works here were similar to Strumpell's in Europe. He added much to medical science through his admirably classified *Practice of Medicine*. Dr. Abraham Jacobi was a pioneer in American medicine, and well deserves the name of the Nestor of American pediatrics. Tinel and Mme. Athenassio Benisty, of Paris, did wonderful nerve repair work during the world war. Carrel and Dakin treated all kinds of wounds and infections successfully with frequent irrigations of chlorinated lime solution named after them. The paraffin and ambrine treatment of extensive burns and surface wounds were developed also during the war and is giving good results. Trench foot, trench fever, and trench nephritis are new conditions for diagnosis brought on by the war.

American Medicine.—The first American medical books were published in Mexico City in 1570-1595. Dr. J. Morgan and William Shippen in 1765 founded the medical department of the College of Philadelphia, known later as the University of

Pennsylvania. In 1767 the medical department of King's College of New York, now known as Columbia University, was founded; the medical department of Harvard University was organized in 1782, and of Dartmouth in 1798. Prior to the establishment of these schools, medical instruction was given by practitioners to their private pupils, except those who studied abroad in foreign medical schools. There was no real American medical literature until after the revolution, when Benjamin Rush (1745-1813) came into prominence. Five medical schools were started in the United States before 1800.

With the rapid expansion of the population in the nineteenth century, it required a much larger number of physicians than the schools supplied. In the absence of restricted law, numerous private schools (medical) were established for profit and gain. A precedent was found in the London medical schools, which were independent of the universities. But in London the medical school was part and parcel of its respective hospital and could not confer a degree. The American medical school had no hospital connection or, in rare instances, an inadequate hospital, and it obtained the right to confer medical degrees, which for many years carried with it the right to practise medicine. Well up into the eighties demoralization was practically complete; in spite of that, medicine and especially surgery made marvelous strides in America in the short time they have been practised here. Much research work, such as animal, bacteriological, pathological, and cellular is being carried on and is constantly adding to progressive medicine new discoveries too numerous to mention. The discovery of anesthesia and most operative technique in surgery is distinctly American. Today America is quite as progressive, if not more so, in many departments of medicine, surgery, and laboratory work, as Europe. The world war has helped greatly to bring together medical ideas of all lands and diffuse this knowledge about evenly in worldly medical events. It will probably be many years before all the new discoveries will be known that were made in medicine during the war.

Medical Education of Women.—The admission of women into medical schools was more bitterly opposed in Europe than in the United States. Until 1900 the medical colleges of Germany were closed to women, and not until 1876 did Parliament pass a bill admitting women into the medical schools of Great Britain; in Paris, in 1871. Now they are permitted to study medicine in Stockholm, Upsala, Madrid, Valladolid, Barcelona, Berne, Zurich, and Geneva. In Russia the war department conducts medical schools for women at Petrograd and Moscow. In the United States in 1848 there was the Boston Homeopathic Medical School for Women; in 1850, the Women's College of Philadelphia; in 1868, the Medical College of the New York Infirmary; in 1870, the Free Medical College for Women. Women now are permitted to study medicine in Johns Hopkins University, the University of Pennsylvania, and Cornell University. In 1911 only two colleges were exclusively for women.

In general, within the past fifty years great prog-

ress has been made in medicine. Undoubtedly in the future preventive medicine will prevail rather than curative, and therefore the subject of diagnosis will be the prominent topic, which we shall describe more fully later.

Practical or applied hygiene and sanitation, physical culture, health education of the laity in matters pertaining to sexual hygiene, the regulation of contagious diseases and inoculations, together with the rising standard of medical education and stricter laws governing practice, will improve the condition of the race until disease will be rare. Many maladies now obscure will be found to be due to one or more perverted functions of the ductless glands, and extracts therefrom will be used. The discovery of infecting agents in such diseases as scarlet fever is only a matter of time. For the past one hundred years experiment has been taking the place of theorizing, and where the early days of medical science present the picture of a few Titans standing out from a background of ignorance, the nineteenth and twentieth centuries show workers in many fields, collecting and collating facts in biology, chemistry, physics, physiology, endocrinology, pharmacology, psychology, accepting nothing as absolute truth, but ever seeking results which shall be truer than former ones, gradually finding out the causes of disease and elaborating a system of preventive medicine which is the hope of the future. Nothing is taken for granted in medicine now; no high flown theorist will be tolerated unless proofs are produced. The patient work of thousands of observant clinicians and painstaking laboratory men is gradually exposing the light of science, and some day empiricism will be entirely eliminated.

Looking ahead as to the possible further development of medicine, it seems to us that the future of this science lies in specialization. Although specialization in the strict sense was not practised in ancient times; still we find a hint of it in the history of Egyptian medicine. Hippocrates also gave definite descriptions of disease and facies, and wrote the Hippocratic oath, his main specialty being dietetics. Dioscorides originated the *materia medica*, and Aëtius was the first real specialist who wrote on diseases of the eye, nose, mouth, and teeth. Later on, as medicine assumed a scientific aspect, it became quite impossible for any one man, no matter how brilliant, to master more than a fraction of the existing field of medicine; specialization therefore became necessary. Among the theoretical specialists we find Gilles de Corbeil, who was the first to confer the degree of doctor of medicine upon graduates of Salerno, in the twelfth century. Roger, of Sicily, was the first hygienist; Paracelsus wrote intelligently on occupational diseases and ductless glands; Henri de Mondeville advocated clean surgery; Vesalius wrote on anatomy; Fallopius as anatomist and gynecologist; Eustachius as anatomist and otologist; Linacre as internist and the first to introduce license examinations to be permitted to practise medicine; Harvey, the physiologist; Malpighi, the great pathologist and microscopist; John Gaunt, the first to write a book on vital statistics, in the seventeenth century; Von Haller, the great surgeon; Auenbrugger, on per-

cussion of the chest; Sir John Floyer, who discovered the pulse rate; George Martini, and the clinical thermometer; Dr. Jenner and vaccination; Turke on care and treatment for the insane; and Lister, who introduced antiseptics and antiseptic surgery. But the more practical medicine began to agree with scientific research, the more specialization became necessary, and in the second half of the nineteenth century division of labor became an established factor in the practice of medicine, bringing forth discoveries from the time of Lister down to the present time.

PRESENT ASPECT OF MEDICAL PRACTICE.

Not so very long ago the family physician was numerically the predominating type of practitioner; at the present time, partly because of the growth of specialization in medicine and partly on account of the great mobility and complexity of our population and of modern life itself, the family physician who treats a particular family continuously and is in close touch with all the members is fast disappearing. Expenses for equipment, x ray laboratory accessories, etc., are too great for the average physician, and health department and commercial laboratories are valuable but limited. This applies not only to equipment but also to the physician's special skill and training. Even those physicians who have had modern training in diagnosis on engaging in private practice often do not have the facilities for using their training effectively for the average patient, or for securing for their patients the services of specialists, because the patient cannot afford their rates. This method of having the patient travel from doctor to doctor or from one specialist to another is used in all classes, but is more prevalent among the well to do and the wealthy. The system is necessarily expensive and is time consuming to the patient, as well as to the physician, who has to be present at the respective consultations at the patient's request, and therefore is not able to work continuously. Besides, the doctor and the patient (separately or together) get independent opinions, often contradictory, and in consequence the physician is frequently at a loss to know the exact diagnosis or how to treat him. This chaotic state of affairs leads the public to seek other means of relief, which accounts for its falling into the hands of charlatans, osteopaths, chiropractors, and other pseudomedical cults. The remedy for that condition is naturally evolving in the form of group medicine practice. The organization of cooperative or group medicine practice is gradually replacing individualism in order to give the maximum of efficiency of equipment and organization of skilled specialists, in order to get correlated medical opinions of trained diagnosticians and as near as possible correct diagnoses of diseases and abnormal conditions.

A number of instances of this tendency are the Mayo Clinics, in Rochester, Minn., the New York Diagnostic Clinics, the Boston Dispensary, and others scattered over the country. These have added valuable data to the medical literature of this century and are in reality institutions for the training of specialists of the highest type, and are also

examples of practical, self supporting pay clinics, diagnosing, correlating data and opinions, and in some cases treating cases and getting results. At the time of the present writing there are about sixty institutions established in America with the group medicine idea. Yet it is not surprising that the real teachers of medicine, the faculties and professors of medical colleges, who should have been the first to advocate any methods that are progressive, fail to recognize this need? It may be expensive to have the proper building, complete diagnostic equipment for every department, and a proper personnel and staff. This may require outside help or large donations, but the group medicine practice plan can be established on a smaller basis with full equipment and trained personnel. Before dwelling on this further, we will define a pay clinic and special dispensary, and then continue with the requisites of a cooperative or group diagnostic medical clinic.

PAY CLINICS.

A pay clinic is one in which a fee is charged to patients, this fee corresponding to the cost of the service rendered. It should therefore be made self supporting. Most of the dispensaries deal with specialty diseases, such as eye, ear, nose, and throat diseases, pediatrics, orthopedics, neurological diseases, etc. The large special dispensaries, existing chiefly in great cities, have contributed substantially to the advancement of specialties in medicine, bringing together a group of physicians or surgeons interested in a particular phase of medical work, and providing excellent equipment for the advancement of special technic.

The essential weakness of a large or small dispensary limited to one specialty consists in an inability to take an all around view of the patient and to relate special conditions to general conditions. If the patient presents himself at a special ophthalmological dispensary, for instance, all the general conditions which may influence a disease of the eye or which may be influenced by eye disease, must be referred to another institution for diagnosis and treatment. The general pay clinic or group diagnostic clinics will solve this problem, in which all departments are well represented in one building for diagnosis. The maintenance of high scientific standards and a spirit of public service, such as generally characterizes private medical practice, are essential in pay clinics.

The group medicine diagnostic idea—self supporting philanthropy—or pay clinics established as a public service enterprise, is a recent development. Patients can be admitted only when referred by a physician, who requests an opinion and report of the case. The charge to the patient should be a flat rate for the examinations, plus extra fees for x ray plates, special tests, such as blood chemistry, complete kidney function, etc., consistent with the circumstances of the patient, but not to be gratis. Free service has a tendency to lower the standard of the clinics and their purposes.

Group medicine practice or group diagnostic clinics should be so organized as to be essentially a cooperative association of a large number of physi-

cians, to prevent skepticism and distrust by the general practitioners of such progressive ideals. This will also greatly broaden the services of the clinics.

The pay clinic may be viewed or appraised from three aspects: 1, the institution; 2, the doctors, and 3, the public.

The Institution.—There is a stimulus to efficient service arising out of the new psychological relation between doctor and patient and between doctor and institution.

The Doctor.—His fees received are gross and not net incomes, considering expenses such as rent, equipment, lighting, heat, records, automobile, etc. In the clinics the physician is supplied with assistants, equipment, plant, and therefore his salary is a net income.

The Public.—It pays less in the end and gets better and more accurate service and results. The diagnosis from correlated opinions, collaborated data and laboratory findings is of the greatest benefit to the public.

Why should not cooperative pay clinics be established by a group of physicians or specialists coming together for cooperative work and having their offices so situated that joint equipment can be arranged? The difficulty would be a defective centralized administration. This, as the experience of all acquainted with dispensary organization and management has shown, is vital to the best cooperative work among physicians, and to the efficient management of the records, laboratory, etc. Where a group of physicians actually established an organization with adequate equipment and complete administrative machinery, the difficulty would be overcome, and we should have pay clinics like the Mayo Clinics for diagnostic purposes, or combined diagnostic and therapeutic. The latter plan may interfere with the practitioner, in that his patients may ultimately wander from his office into the clinics, whereas in the former or group diagnostic clinics, the patients are referred back to the physician who recommended the case, with full data of diagnosis and suggestions as to proper treatment. The physician may report from time to time the progress of his case, for follow up work and tabulating results. The fee should be scheduled so that those of small means, as well as the rich and well to do, might benefit. In general medicine and most of the specialties, especially in diagnosis, there seems to be a considerable field for cooperative medical clinics. The encouragement of pay clinics of either type is a measure of progress in the development of cooperative or group medicine practice on a democratic basis.

The efficient dispensary of the present day needs correction of three faults: 1, A medical organization not sufficiently centralized so that the patient is divided up between clinics without adequate central medical control and interpretation; 2, too much hurry, too many patients for the time allotted for the examining physician, hence too little comfort and too little dignity for the patient; 3, lack of adaptation to the needs of a clientele of wage earners. The group medicine clinics obliterate all these defects.

NEEDS FOR AN EFFICIENT DISPENSARY.

1. A medical staff properly remunerated for its services.
2. A medical organization facilitating cooperative diagnosis and treatment, providing central medical control, interpreted data for reference of the attending physician.
3. Central administrative control of all its branches of dispensary service, carried out by an efficient executive officer, under a board of committees in which the medical interests of the staff and the interests of the laity are both represented.
4. Administrative organization to secure reasonable comfort, privacy, and dignity for the individual patient.
5. Building and equipment of proper standard, good nursing, good clerical staff, and a good social service department.

Although ideals are seldom if ever attained, still the nearest to the ideal seems to be the type of the Mayo Clinics, of Rochester, Minn.; New York Diagnostic Clinics, New York, and the Boston Dispensary, Boston, Mass. We shall give a brief description of the New York Diagnostic Clinics, since it is of the latter we have direct personal knowledge.

These clinics were organized by the New York Diagnostic Society to provide facilities for group diagnosis of cases among all classes. For this purpose the clinic is divided into nineteen separate clinics or departments of modern medicine. These are adequately equipped with all modern diagnostic devices and instruments, including complete modern laboratories for pathological, bacteriological, and animal research work.

The medical staff consists of one chief and two assistants, on a six months' service in each of the nineteen departments, and several full time men who are in the laboratories, general x ray and dental x ray departments, and the anamnestiologist. Physicians receive final appointment only after the expiration of a year's satisfactory service. They must be of the highest type, as to their experience and knowledge in their respective specialties, as well as their character and standing in the medical profession and medical societies. The institution is in fact a composite of the diagnostic facilities to be found in the leading hospitals and dispensaries of the United States and Europe. It is worthy of study for those interested in model clinical and dispensary work as an inspiration for the establishment of similar clinics elsewhere.

CONCLUSIONS.

The advantages of cooperative or group medicine practice for all social classes become more generally perceived. Is the practical situation of the medical profession satisfactory? Would a larger and more general preparation in the work of cooperative clinics improve the financial outlook and status of the rank and file of the medical profession? The answer is decidedly, yes. A higher average income and more stable income and a larger professional opportunity for the average physician, who has had a good training to start with, are desiderata which can

only arise out of more comprehensive organization, which means essentially more work done in medical institutions and more cooperative and collaborative practice.

The world will not fail to remember, however, that the advances in modern medicine which have been made during the world war could only be brought about by cooperation of the medical fraternity in all fields of military medicine and surgery, hygiene, and sanitation. Hence the advantage and necessity of pay clinics with the group medicine idea, which should be the future progressive way for successful practice of medicine.

Twenty-eight years ago Dr. Stephen Smith, a well known clinician who has added much to medicine in our country, remarked at a meeting of the Academy of Medicine: "I predict that in twenty-five years the United States will be the medical Mecca of the world." Therefore, one of two things is necessary, either that a combination of men interested in the various sides of medicine club together primarily to arrive at diagnoses, so that any one of them can cover any scope in therapy demanded in a case, or that we develop a new department, namely, that of the diagnostician, to whom medicine will eventually look in the future.

The sins of omission and commission on the part of different men in the various branches of medicine naturally prompt us to seek for diagnosticians. In the future, this want will become more and more urgent, and it will not be many years before the people will demand such service. Let us in this instance be progressive enough to supply this need when it arrives.

I am greatly indebted to Dr. M. J. Mandelbaum, medical director, New York Diagnostic Clinics, for his valuable suggestions and material aid.

125 WEST SEVENTY-SECOND STREET.

Prostatectomy.—Henry G. Bugbee (*Boston Medical and Surgical Journal*, July 15, 1920) emphasizes the following: 1. The study of prostatic obstruction has had slow evolution, extending back over two thousand years. 2. Not until it became possible to inspect the interior of the bladder were measures for its relief placed upon a definite footing. 3. With the advance in the study of cases, operative measures suggested during the period of obscurity were brought forward and perpetrated with renewed zeal. 4. Anatomical and pathological study of cases has resulted in a certain classification. 5. The objects of relief will best be attained by a thorough analysis of the individual, by procedures instituted to remove step by step and with the least possible shock to the patient the causes of the symptoms. Prostatectomy for fibroadenomatous enlargement can best be accomplished by preliminary suprapubic drainage, the removal of the gland being an incident of the convalescence from the drainage. The most important phase in its removal is the control of hemorrhage, with a careful attention to details during the healing, insuring a rapid functional cure free from complications.

BINOCULAR SINGLE VISION.

By GEORGE W. VANDEGRIFT, M. A., M. D.,
New York,

Instructor in Ophthalmology, Cornell University Medical College.

Binocular single vision, or the fusion of two retinal images of an object into a single perception, offers a subject for investigation of more than ordinary interest. Many investigators consider it a visual function rather than a secondary result of ocular activities. Its utility cannot be gainsaid but a little thought will show that it plays a minor rôle to the prime purposes of vision, that of perception of the external world and protection from its vicissitudes. Binocular single vision far from being a purposeful function is a compromise in the play of evolutionary processes. The proof of this lies in the study of the biogenetic development of the visual apparatus and in the study of the factors by which binocular vision is harmonized and antagonism prevented.

It is established that the visual field is divided into two purposeful areas, that of the fovea or central area which is concerned with the nice distinction of details and form, and that of the periphery which is to a high degree sensitive to movement and to the differences of illuminations. In the lower vertebrates the fovea is absent and visual acuity is low so that the search for food and protection must depend largely upon the movement of objects. Birds and higher monkeys are supplied with a fovea and keenness of central vision is added to the quick perception of movement.

Among the invertebrates a binocular field of vision must be extremely rare as the eyes possessed by the different species vary enormously both in number and position, though in most animals that propel themselves the eyes are in the anterior segment of the body. In the cuttlefish and crustaceans the paired eyes occupy a position that possibly may produce an uncertain amount of binocular field. Among the vertebrates a binocular field is generally present except in fish where it is found exceptionally, only among some of the deep sea varieties.

Depending upon the relative positions of the orbital axes for its limitations, and upon the stage of development of the ocular muscles for its range, the binocular field varies markedly in the various subdivisions. Throughout the animal series the biorbital axial angle varies widely. In man and the higher apes the binocular field is large, approximately 120° ; but with increase of the biorbital angle in lower animals the extent diminishes. In the carnivora it approaches more nearly the size found in man, being approximately 100° , while in ruminants it decreases to 50° , and in birds to 30° . The binocular field is not limited necessarily to an anterior position for with an upward or backward displacement of the eyes a binocular field may develop superiorly as in a few amphibia and rodents, or posteriorly as in the albino rabbit. In a few of the lower animals such as the carnivora and herbivora the increase of the biorbital angle appears to be counteracted by the increased size of the corneal surface by which the monocular visual angle is enlarged and the binocular field maintained.

In all classes of vertebrates the extraocular muscles are well developed except in reptiles and birds, in which the movements of the eyeballs are much restricted. Animals in which the head movements are restricted, such as the fish, possess a highly developed extraocular muscular system, and those in which the head movement is free, as in birds, have, as a rule, a more limited extraocular muscular activity. This rule is not without exception, however, as many animals requiring a quickly shifting field of view for the detection of prey and for protection, as the carnivora, are supplied not only with muscles of rotation which at times, in addition to the ordinary movements as found in man, may possess the power of projecting the cornea beyond the lids, but also are supplied with a muscular system not found in man, which allows translation of the globe.

Whereas the extent of the binocular field depends upon the size of the biorbital angle and the range upon the external musculature, the perceptive intensity within the field varies with the acuity of vision, central and peripheral, and with the degree of development of the functions of convergence and accommodation. Central visual acuity varies widely among the vertebrates. In the higher groups only, such as birds, apes and man, does a fovea exist and a powerful accommodative apparatus. The lower vertebrates, having no fovea, must be visually guided by the movements of the external world. Tracing the development of the ocular apparatus we find no valid reason to judge the human eye as the highest or most perfect type. Anatomically and physiologically it occupies in development a place below that of birds. With the evolution of mental characteristics a perfection of other functions is not so requisite as in lower animals not so endowed. The ocular apparatus displays throughout the animal kingdom a demonstrable and excellent adaptation of form and function to environment. The lowest vertebrates, such as fish and reptiles, appear to orient themselves largely by external movement. The herbivora also appear to have a visual acuity available for a short distance and protection and the search for food must depend visually upon a keen perception of movement. The carnivora are better endowed with a perceptive retina and accommodative apparatus though the fovea is absent. The monkeys nearly approach man in the development of the eye, while the birds, in which the retina is highly developed and possesses one or more fovea, have a visual acuity and accommodative apparatus of a degree unapproached by any member of the animal kingdom.

The complete visibility of the external world demands not only orientation and the perception of objects but also the realization of their spatial relations of distance, depth and comparative sizes. For this psychological conception are necessary not only the factors previously described but also that factor derived from the muscle sense produced by accommodation and convergence.

An accommodative apparatus is not exclusively a property of the vertebrates. A functioning lens is found in many invertebrates. In very simple forms such as the snail it is in contact with the retinal cells

and refraction and accommodation are practically negative. Such a primitive apparatus determines only the direction of the light source. For the formation of an image, indistinct as it may be, an eye fashioned upon the principle of the camera is necessary. Such a compound apparatus is found among many invertebrates as crustaceans, insects and worms. Among the worms the first details of a ciliary body appear as a group of small pigment cells between the lens and the retina. In the cuttle fish a distinct ciliary body is discoverable which is attached to the lens and moves with its excursions. In other shell fish such as the pecten the ciliary body consists of a muscular apparatus so arranged as to increase by contraction the convexity of the lens.

While the accommodative act is present in all vertebrates its mode of accomplishment differs in many species. In fish the anteroposterior excursions of the lens vary refractivity. In the bird the act of accommodation is performed secondarily by a similar excursion of the lens and primarily by an increase in curvature of the cornea. Mammals, apart from man, have a weak accommodative apparatus, the mode of activity of which is the same throughout the subkingdom, and needs no elucidation here.

All these factors, the multiplicity of eyes in the invertebrates and their varied positions, the variations in the direction of the orbital axis of the binocular invertebrates and vertebrates, the irregular development of the visual angle and of the external and internal musculature, are directed to the accomplishment of a visual acuity and orientation demanded by environmental exigencies of protection and search, and not to the creation of a binocular single field. The latter describes no regularity of development, and results secondarily when these factors are so coordinated as to bring it into existence. As we shall see a true conception of the visible world and its spatial relations is as possible monocularly as binocularly, the latter furnishing only an increased precision and nicety. Finally, considering the high psychological laws involved in spatial apprehension it is a debatable question whether the binocular field plays any but an adventitious rôle in the animal kingdom below man.

We have traced briefly the anatomical and physiological factors that develop the binocular field. Before studying the factors that maintain single vision within this field a psychological analysis is requisite of the mental concept that produces in consciousness the knowledge of the external world as a material entity of three dimensions. Observers generally look upon binocular single vision as a necessary function in the production of this concept. The apprehension of spatial relations is not, however, dependent upon binocular single vision for it is present though distorted in pathological diplopia, and also in those individuals whose vision is performed monocularly. The concept of space is a compound of qualitative and intensive sensations dependent not only upon visual but also upon tactile and muscular perceptions. Such sensations are, however, of themselves not sufficient to produce a true knowledge of the external world. Upon these must rest a power of consciousness that is constructive, so that the apprehension of space is the product

of experience through the interaction of the association of ideas upon the qualitative sensations. Otherwise the concept is intuitional. The spatial errors of young children and of the blind restored to sight appear, however, to refute this latter hypothesis. Based thus as it is upon highly developed psychological interactions this concept of spatial relations can be present but dimly, if at all, in the low orders of the animal kingdom which may possess a binocular field even more extensive than man's. The processes of evolution appear to have produced adventitiously the overlapping fields by placing the ocular apparatus in the position that gives the widest outlook. In the higher animals, in which the apprehension of spatial relations begins to enter consciousness, secondary factors have been evolved to refine and to maintain the concept undistorted within the binocular field. Were binocular single vision and its refining and maintaining factors a primary rather than a secondary process we would expect to find young children and the blind restored to sight endowed at the incipiency of visual activity with a full and exact apprehension of spatial relations. The earliest apprehension of distance and of surface extension however depends upon the tactile sensations. In the first few months of life the binocular movements are incoordinated and the power of accommodation undeveloped. When the size of objects and their distances apart are apprehended by grasping visual apprehension develops and objects and distances previously acknowledged consciously through the sense of touch become the foundation of visual apprehension. With full development of the latter the conception of space is further clarified by the muscular sense produced by accommodation, convergence and orientation.

Analyzing the concept still further we find that the apprehension of space is extensive while the sensations giving rise to it are successive. Both the tactile and visual images are connected continuously and without interruption though the tactile and visual organs lack this relative continuity, the retina in fact containing the blind spot which is not projected into consciousness. Again we are led to the conclusion that the concept of spatial relations is the product of a power of consciousness that is constructive, and that binocular single vision while a contributing factor cannot be the controlling influence in its creation.

To maintain this concept clear and undistorted within the binocular single field certain psychological and physiological factors must functionate harmoniously. The primary psychological factors are the faculty of fusion by which the two retinal images are merged into one perception, and the faculty of projection by which the retinal impression is projected along the line of direction into the visual field, passing through the nodal point, and thereby furnishing the knowledge of direction and position. These functions are undoubtedly mental. They do not produce the concept but refine it and prevent antagonism within the overlapping fields. Were the spatial concept based upon innate ideas the fusion and projection faculties would be found completely developed at the first visual act. The first evidence of their presence is not manifested how-

ever until several months after birth and they are not fully developed for five or six years.

Within the binocular field the sensations received at the two foveæ are projected to the same place in space if the two eyes functionate normally. If the gaze of the two eyes is directed through two openings of interpupillary distance in a sheet of paper held close to the face the two openings appear as one lying in the median line. Impressions received upon peripheral retinal parts, however, are fused only when they fall upon identical retinal points.

Under the impulse of the spatial perceptions the will controls the actions of the two eyes as though they were a single organ; and the nervous impulses that produce ocular movements are of equal binocular intensity. Each eye is the duplicate, anatomically and physiologically, of the other. Each macula has a common brain cell connection with the other, and every perceptive point in each retina has a corresponding perceptive point in the other retina anatomically connected. Thus two images may be fused into one when the images are produced by these corresponding points. Corresponding points are, therefore, anatomical and physiological facts upon which the psychological factors of fusion and projection develop.

A perceptive point in one retina corresponds with a perceptive point in the other when images upon them of the same external object are projected as one. When, however, the images are not blended diplopia results, for the perceptive points are not identical.

Every visual act embraces a field of view that is complex. Objects occupy every possible plane in relation to the visual line. The eyes rapidly pass from point to point, orienting themselves, converging and accommodating. In each visual act, therefore, a large number of objects do not fall upon identical points. For every direction of the gaze certain objects which lie in space so as to fall upon identical points appear single, while all other objects falling upon nonidentical points produce a physiological diplopia. This, however, does not cause confusion, but rather adds to the delicacy of the spatial concept. The blurred peripheral images act as directors of the visual line so that the eyes easily pass from point to point estimating distance and direction. A complete concept of the field of view combining perspective and stereopsis is thus obtained, and the double images being closely associated and falling upon retinal parts of low perceptivity do not produce diplopia in consciousness until the attention is drawn to it voluntarily.

While the sense of direction depends upon the faculty of projection the realization of form size and distance rests largely upon the muscular sense. Muscular perception arises not only from the interplay of the conjugate muscles but also from the action of convergence and accommodation. The muscle sense is complicated, being compounded of the sensations derived from muscular activity and from their mental interpretation. The tension or effort of the muscular action and the result or the muscular contraction accompany the voluntary mental control and produce in consciousness a knowledge

of the intensity of impulse demanded for a particular action. The knowledge of direction, therefore, and indirectly of the size and distance of objects, depends upon the consciousness of the degree of energy required to bring the visual line into that direction. Once again we perceive that the spatial concept is not innate but founded upon knowledge derived from experience.

The previous discussion has dwelt largely with the apprehension of the first and second dimensions of space. We have seen that the spatial concept does not rest entirely upon ocular sensations, and that binocular single vision is not so essential that its absence would prevent the production of the concept. The apprehension of depth and relief, the realization of the third dimension of space, likewise is not exclusively a binocular function. Monocularly the apprehension of the third dimension may be derived in many ways. Stereopsis or the sense of relief may be produced monocularly by the effects of shadows and shades and by mathematical and aerial perspective. From accommodation and from parallax movements of objects when the eye or head is moved the knowledge of distance and anterior posterior extension is derived. Solidity is thus realized.

Binocularly stereopsis and perspective vision are more exquisite and refined. As an object may now be perceived from two different aspects the sense of solidity is heightened. This constitutes stereoscopic vision. Perspective vision is the perception of objects at varying distances, the knowledge derived from the muscular actions of convergence and accommodation furnishing a sense of depth.

It is not essential in this brief review to enumerate the various factors existent in the external world, such as shadow play and relative sizes and distances of objects, that enhance the sense of depth and relief; nor is it essential to analyze more fully the subjective elements of stereopsis and perspective. The purpose of this paper is to analyze the spatial concept and show that it is not entirely an ocular production; and that while the function of vision is a primary factor the concept may rest upon monocular as well as binocular perceptions. Biogenetically the binocular field and its manifestations have been evolved not to produce the concept but, having been evolved secondarily, have been developed to conform to and not to antagonize the concept.

The sense of solidity and depth are neither essentially ocular, tactile nor muscular but a complex of these sensations acted upon by the association of ideas, in which memory and experience play an important rôle. The completed concept is the result of a constructive mental function.

Treatment of Tuberculosis Epididymitis.—H. Wildholz (*Schweizerische medizinische Wochenschrift*, June 17, 1920) discusses the advantages and disadvantages of excision of the epididymis in this condition, and seems on the whole to favor this operation. Yet the psychological injury produced on a young man by a double castration is so great that it cannot be recommended. In a great many cases also the disease is too far advanced for an excision of the epididymes to be effective in checking it.

PRESENT STATUS OF RABIES.*

Clinical and Microorganismal.

By B. M. UNDERHILL, V. M. D.,
Philadelphia.

As to the present status of rabies, I can bring little before you but what is of common knowledge to medicine, for I am not aware of anything new having been reported from research in this line during the past two or three years. Probably all warm blooded animals are, in varying degree, susceptible to this disease which has been termed rabies, lyssa, canine madness, or hydrophobia, all of which terms, except the last, may properly apply to it in lower animals, the dread or fear of water never having been observed in these, though, whether or not a true specific symptom, it does appear in man.

So far as I know, Noguchi, of the Rockefeller Institute laboratories, has made the most recent report upon investigations with Negri bodies. This deals with the cultivation of the parasite, as he terms it, of rabies. Noguchi undertook to cultivate the virus of rabies from the brain and medulla of rabbits, guineapigs, and dogs infected with street virus, passage virus, and fixed virus. His results were obtained by methods employed for the cultivation of spirochetes of relapsing fever (1). His cultures were minute granular bodies which, on transplantation, reappeared in new cultures through many generations. He observed that in the cultures from passage and fixed virus, round or oval nucleated bodies surrounded by membranes appeared. He demonstrated the cultivated nucleated bodies actively multiplying by division and budding, and exhibiting the appearance of protozoa. In size they were one micron to twelve micra. By inoculating cultures containing the granular or nucleated bodies he has produced rabies in dogs, rabbits and guineapigs with typical symptoms and positive animal inoculations.

It might be said here as to the terms street and fixed virus that street virus is from rabid dogs naturally infected. When street virus is inoculated into a rabbit it reproduces the disease in fourteen to twenty-one days or more. This street virus is then conveyed from rabbit to rabbit through a number of transfers. It thus becomes more virulent for rabbits and the period of incubation of the passage virus is progressively shortened. Finally the rabbits invariably sicken on the sixth or seventh day and die on the ninth or tenth. When the virus has reached this degree of virulence for rabbits it is said to be fixed, that is its potency remains constant. Fixed virus, which has obtained a high degree of virulency for rabbits, has lost much of its virulence for dogs, and is probably avirulent for man.

For the Pasteur treatment the fixed rabbit virus is used. The rabbits are injected with the fixed virus under the dura mater. A rabbit thus inoculated should begin to show symptoms in six to seven days and die on the ninth or tenth day. The spinal cord is then removed and hung in a jar containing potassium hydroxide. Jars containing the cords are kept in a dark place at a temperature of 20° to

22° C. Under these conditions the cords gradually desiccate and the virus diminishes in virulence until the fourteenth day, when it is no longer infective. Pasteur started treatment with a cord fourteen days old. A small portion of the cord is ground in sterile salt solution and injected into the subcutaneous tissue of the abdomen.

The original method of attenuation of virus and treatment of Pasteur has been modified in many ways. Many Pasteur Institutes now start treatment with an eight day instead of a fourteen day cord. "Ferran in Barcelona, Proescher in Pittsburgh, and others inject patients with the unaltered, fresh, fixed virus. The advantages in using the virus as fresh and as strong as possible are that an active immunity is produced more quickly, and this is of considerable importance in wounds of the face, also in wolf and cat bites, which frequently have a short period of incubation. Further, only one or two injections of the fresh virus are necessary to produce an immunity, and this shortens and simplifies the treatment very much." (2)

Proescher (3) injected into himself the entire brain and medulla of a rabbit (fixed virus), and another entire brain into a volunteer with no ill effects in either case. A control rabbit injected with a 0.02 dilution of the same emulsion died in seven days with experimental rabies.

In the laboratory of the Pennsylvania State Bureau of Animal Industry our method of examining material sent in for diagnosis where rabies is suspected is as follows: The brain and ganglion nodosum, (the second ganglion of the pneumogastric) are removed. Impressions are made upon slides from the transected hippocampus major and from the cerebellum, and portions of each, with the ganglion nodosum, are placed in eighty per cent. alcohol for sectioning. Portions of the hippocampus and cerebellum are also placed in glycerine for animal inoculation should it be desired that this be carried out. The impressions are fixed in methyl alcohol for a few minutes, dried, and stained with:

Sat. alcoholic sol. carbol fuchsin.....	1 c. c.
Loeffler's methylene blue.....	30 c. c.
Water, q. s.....	100 c. c.

Heat upon slide, simmer and allow warm stain to remain for about thirty seconds.

Examined with oil immersion lens, the nerve cells, if properly stained, will be blue, the Negri bodies a maroon red with one or more dark stained inner bodies. Careful impressions show the bodies within the cytoplasm of the nerve cells. If the brain material is more or less smeared upon the slide many of the bodies will appear as extracellular in the spread cytoplasm. Sections are stained with hematoxylineosin or with the Mann stain.

During twelve months in 1915-16 thirty-three brains of dogs dead from causes known to be other than rabies were examined in our laboratory. All were treated in the routine outlined for examination for Negri bodies. A thorough search of this material failed to reveal any intracellular or extracellular structure that could be regarded as a Negri body, and in no case were there changes in the ganglion.

As to the reliability of changes in the ganglion in the diagnosis of rabies, some investigations were carried out in our laboratory for a period covering

*Read before the Pathological Society of Philadelphia, March 25, 1920.

two years in 1914-16. Four hundred and fifty-three brains of dogs were examined, sections of the ganglion nodosum being made in each case. In 223 of these both brain and ganglion were positive, in 187 both brain and ganglion were negative, in nine the brain was positive, ganglion negative; in thirty-four the brain was negative, ganglion positive. In the last case it is probable that the Negri bodies escaped observation in the brain examination, or that the material, through decomposition, mutilation or other cause, was in unsatisfactory condition for preparation and staining. From these findings we concluded that in all cases submitted for diagnosis the ganglion nodosum should be preserved and, in the event of negative brain findings, examined. If the sectioned ganglion showed diffuse or distinct localized proliferative changes it warranted a diagnosis of rabies.

To the practiced laboratory worker frequent observation of Negri bodies stamps them with such morphological and staining characteristics as to make it unlikely that he will confuse them with other corpuscular elements. Accepting it as true that these bodies are only present in the central nervous tissue of animals which were suffering from rabies at the time of their death, the case is at once returned as positive to rabies where the bodies are found.

It is not within our province to advise as to the treatment of persons bitten by animals suspected of rabies; that is a matter at the disposal of the physician in charge. In the event of advice being asked for, we would suggest the following:

1. While the presence of Negri bodies is proof positive of rabies, failure to find them does not warrant a negative diagnosis. If an animal has exhibited symptoms of rabies treatment should be given, though no Negri bodies and no ganglion changes have been found in the material submitted. This is especially true if the animal has shown changes in disposition, expression and voice, a tendency to roam, an unusual disposition to bite, or partial dropping of the lower jaw.

2. If a person has been bitten by an animal, and the animal is securely confined so it can do no further harm, it should not be killed unless distinctly rabid. If killed before or during the initial symptoms it is probable that changes in the central nervous system will not have had time to develop; laboratory examination cannot aid, therefore, in removing the uncertainty. If the confined animal lives and remains normal, Pasteur treatment of the bitten person will be unnecessary. If rabies develops in the animal within a week or ten days following the bite, treatment of the bitten person is advisable as the saliva may already have become infective. The confinement and observation should extend over a period of at least two weeks. Dogs usually die in a few days from the inauguration of symptoms.

3. While the period of incubation is in any case of natural infection far from exact, clinical experience has shown that this period is shortened relative to the proximity of the seat of inoculation to the brain. Face bites, therefore, call for more prompt and intensive treatment than those upon the hand

or leg in order that immunity may be established before expiration of the incubation period.

In any review of rabies a case is made out against the dog as the principal offender. Through his susceptibility and tendency to roam and to bite, he is the reservoir and disseminator of the disease. In general, the dog has certain qualities which tend to make him attractive to man, while, on the other hand, he has characteristics of habit which, to sane minds, brand him as a disgusting nuisance. Restricted and properly cared for by a responsible owner, he may well be tolerated; unclean and without restraint, he is a menace to public health. He harbors more intestinal parasites than any of our other domestic animals, and certain of these can readily be conveyed to man. Through the dog's intimate association, especially with children, he runs a close second with the house fly as a direct transmitter of pathogenic bacterial and parasitic organisms. It is well known that the dog furnishes essential hostage to stages in the life history of certain parasites of man, as well as parasites to other animals used as human food.

Echinococcosis occurs in man, cattle, sheep, horses, hogs, and numerous other animals. The hydatid is derived from ingested material contaminated with eggs from a three segmented tapeworm (*Echinococcus granulosus*) about three sixteenths of an inch long, which may inhabit the small intestine of a dog by the hundreds. The dog is practically the only carrier of this tapeworm. In domestic animals the cysts are commonly found in the liver, usually multiple, and may reach the size of an orange, or maybe larger. In these animals the hydatids are seldom, if ever, fatal. The longevity of lower animals, especially those used for human food, is relatively short, and the cyst, a slow grower, probably does not reach its full development. In man, where the development has not been checked, the hydatids are said to reach the size of a child's head. A common tapeworm of the dog, *Dipylidium caninum*, may also infest man, principally children. Hall speaks of a case in which as many as two hundred and thirty-eight of these worms were found in a single person. The intermediate host of the worm is the dog flea or louse, probably in most cases the flea. Infestation with the tapeworm is by ingestion of the flea containing the larva (*Cryptocystis trichodectes*). Children in their intimate association with dogs, especially if they have food, as sticky candy, about, may easily have a flea or two conveyed to the stomach. The larval worm is there set free and, passing to the intestine, attaches to the mucosa by its armed rostrum and sucker disks and proceeds to develop the strobila which may reach a length of about fourteen inches.

A round worm of the dog, *Toxascaris limbata*, may find hostage in man's intestine. The infestation is direct by ingesta contaminated with the worm's eggs. Dogs are also accused of playing a part in the spread of diseases due to fungi, such as ring worm and favus.

PROTEIN FEVER.

By GEORGE F. COTT, M. D.,
Buffalo, N. Y.,

Professor of Otolaryngology, University of Buffalo.

At various times and places the otologist sees patients with suspected sinus thrombosis, or mastoiditis; whichever it may be, it needs draining; then the patient recovers, or succumbs, or hangs in the balance indefinitely. These balance cases are encountered in other diseases besides those found in otology. We will, however, consider only those which would interest us most, namely; diseases of the ear.

My observations on these balance cases extending over a period of fifteen years were mostly on post-operative cases, but they occur just as often before. I have found that patients often have a vacillating temperature of such extreme variations that it makes the physician worry, not as to cause, but as to result. When a patient is seen but once a day the thermometer may read from 104° to 106° F. every day for a week or more. If a record were taken every three or four hours he would find that the temperature recedes after a short high spurt, and repeats that performance, usually every day or so. A physician with considerable experience will at once think of sinus thrombosis. So typical a temperature will only be found where the channels are peculiarly situated as those within the skull cavity. There are sharp as well as obtuse angles in the various brain sinuses, such as obstructions found at the jugular bulb and veins entering the sinus at right angles. All these further the formation of clots. Particles are then swept into the blood stream causing certain disturbances which will be described later.

A thrombus is always a pathological condition but may not be septic. Bacterial invasion may be checked spontaneously before operation or afterwards. Bacteria may not be pathogenic unless they are able to propagate by feeding on the surrounding medium. While growth continues proteolytic enzyme is being formed, or the cell is being sensitized (which we will designate as the period of incubation) and as the poison in the circulation comes within the sphere of the cell it is digested with the evolution of heat. When, however, the bacterial cell protein is overwhelming, instead of a rising temperature we may have a falling temperature and a consequent depression. The severity of the symptoms depends entirely upon the degree of infection.

On the other hand, if the foreign protein is not infectious and is introduced at frequent intervals then there are often no marked symptoms except a high and low temperature, rising during digestion and gradually dropping again to normal at its conclusion. A marked chill may also occur though usually there is only a rise of temperature. Chilly sensations up and down the back are quite common. Unless protein from a thrombophlebitis is infectious it is digested with the elimination of heat, but there are no symptoms of depression. When the foreign body is large enough it may obstruct certain vessels, be-

coming an embolus. This condition is out of the category of this discussion.

When we come in contact with different zymotic diseases such as typhoid, scarlet fever, or spotted fever, we at once paint a mental picture, not only of the causative factor, but also of the destruction in progress. We know the effect produced in typhoid fever in the spleen; the skin in scarlet fever, and the meninges in spotted fever, and because of these ocular manifestations we are accustomed to follow the ancient observers and apply a name to an effect. If we would investigate closely we would find that all poisons of infection are the same. Different bacterial proteins manifest their predilection for certain cells only, and then we may have hay asthma affecting the air passages; typhoid, the spleen; rheumatism, the joints, etc. A protein, not being a toxin in itself, does not develop or propagate in the surrounding medium and therefore is easily disposed of by digestion and fever, without much more general disturbance. For that reason one can usually give a favorable prognosis and not subject the patient to unnecessary worry which produces no good, but perhaps a tedious convalescence.

For a number of years I have contended that

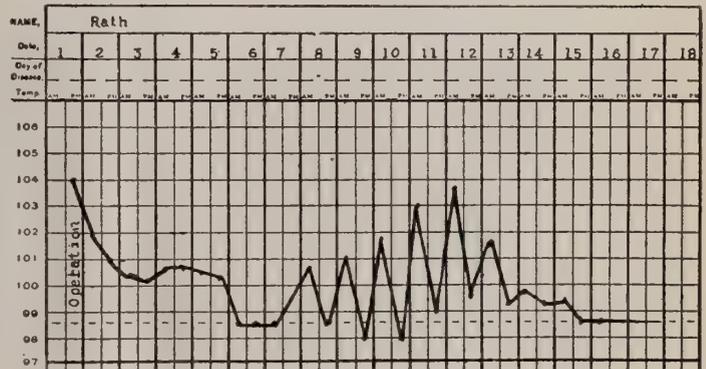

CHART I.—Radical mastoid operation. Sinus thrombosis, which had broken down and formed pus in centre; epidural abscess. After operation temperature fell to normal; after the seventh day temperature rose and continued to rise and fall for a week, then gradually recovered. At the height of the fever, which reached 104.5°, the consulting surgeon said the patient would die; I disagreed. The patient recovered.

typical temperature of protein digestion is not septic or due to infection. My remarks were greeted with a smile of incredulity in certain quarters. Therefore, I thought it best to make a somewhat more elaborate statement and emphasize the difference between infectious and noninfectious substances.

Many of us have encountered cases with temperatures simulating sinus thrombosis and have operated upon the patients and found practically nothing. If we would take into account that it requires more than temperature to prove the existence of a septic clot in one of the brain sinuses, we should hesitate before coming to conclusions. I do not wish to convey the impression that one runs much risk in opening the sigmoid sinus, but it may cause much delay in a patient's recovery.

My attention was first attracted to such a condition in a physician. My impulse was to open the sinus and this course also met the approval of a surgeon and an internist, both men of large experience. I hesitated because the patient's temperature

after five or six days remained normal for twenty-four hours and then took another sprint upwards. I counseled watchful waiting. Then scrutinizing accompanying symptoms I decided that I could safely take a chance, and the patient recovered.

constant, but remitting from time to time. This fever is caused by the sweeping into the circulation of infinitesimal particles of the new clot, causing a rise in temperature. Each succeeding particle produces the same effect. If bacterial invasion continues and thrives within the clot they will be swept into the circulation producing not only spurts of high temperature but also delirium, nausea, chills, sweats and in general marked to profound depression, as in bacteremia. On the other hand, when bacterial propagation has been checked or become arrested, from some cause or other, it happens at times that the particles keep on being swept into the circulation as before until the clot is finally set. This is not an occasional occurrence but I believe quite common. Fever is produced which causes alarm. It is just this latter class of cases that seems to bother the otologist and the surgeon from time to time. They occur before an operation or after one, but always cause concern. Before considering the cause and

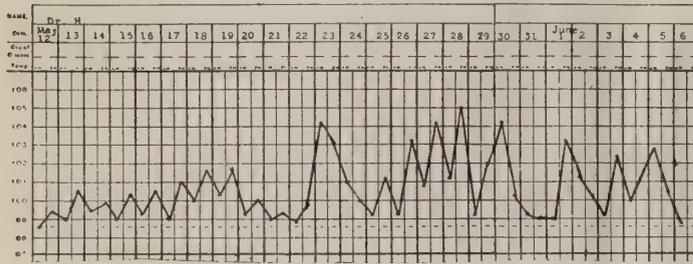

CHART II.—Radical mastoid operation. Caries. Fifth day after operation, temperature rose and continued to rise and fall for a week. At the end of that time, in consultation with two eminent men, an internist and a surgeon, it was decided to explore the lateral sinus. But the next day the temperature returned to normal and I put off operation. Final recovery.

Since then I have had a number of such experiences and in every instance I gave a favorable prognosis without further operation, and all of the patients eventually recovered. Some years ago I presented a paper on this subject before a local society, in the discussion of which Dr. Bentz, a Buffalo pathologist, said I might find a solution of the problem in the experiments of Vaughan which he conducted during a period of fifteen years and which can be found in his book (1). The conclusions given here are entirely drawn from Vaughan's work. Although it is only theory it is so palpable and his experiments so exhaustive that I can but accept the conclusion drawn therefrom.

Let us draw a mental picture of a case with suppuration of the middle ear and phlebitis of a sigmoid sinus, or symptoms which would lead us to think the sinus was involved. First we have irritation of the wall, its endothelium becomes desquamated, its walls softened, thickened and sometimes disintegrated, coagulation of blood occurs in the vessel. Up to this time we may have had no symptoms referable to sinus thrombosis.

Now, however, the patient begins to show signs of fever, that is, bursts of fever, not continuous or

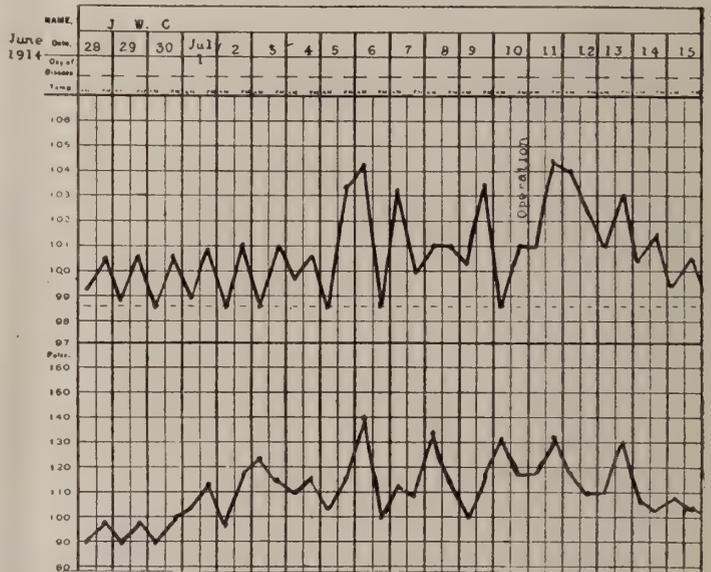

CHART IV.—Mastoid disease. Patient thought to have typhoid fever; after two weeks drum head ruptured and discharged pus for about ten days, when I saw him. His trouble was supposed to be acute mastoiditis. Found sclerosis due to recurrent attacks; mother denied previous ear disease, but acknowledged boy had complained of earache off and on. Red cells, 4,250,000; white cells, 10,000. Lingered for several weeks after he left hospital, then recovered.

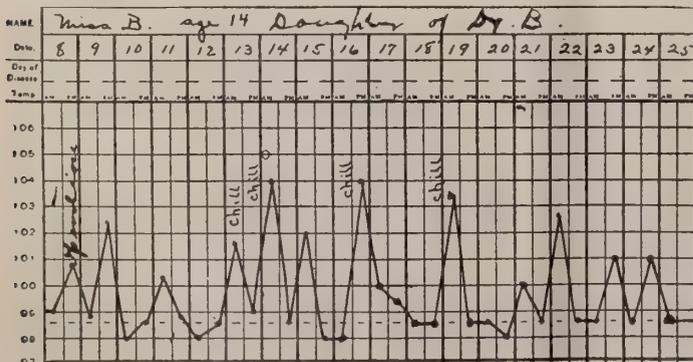

CHART III.—Mastoid disease. The peculiar temperature caused an examination by the physician and a surgeon, and they concluded the patient had endocarditis. The only murmur heard was over the left scapula toward the vertebræ. Recovery.

giving a valid and plausible explanation for it, I want to emphasize the fact that these cases are not septic and do not end disastrously. But to differentiate one must notice that although the temperature is of the recessional type the patient does not become worse from his fever, is not nauseated, delirious nor depressed. His leucocyte count is seldom over 10,000; he feels comfortable, smiles, eats with considerable relish, and sleeps three or four hours at a stretch. In fact he complains of little. Some have chills, to be sure, and perspire afterwards while others perspire only after their spurt of temperature but they all eventually recover. The temperature differs from the virulently septic type in this way, that every few days it remains normal,

this way, that every few days it remains normal,

to resume its flight again after this period of rest. When a septic temperature comes down to stay it means either recovery or death. This is not so in protein fever. Now let us look into the cause of this peculiar phenomenon.

A protein molecule introduced into the circulation whether enteral or parenteral is a foreign body and must be removed. It is the business of a similar protein cell to perform that duty. When the foreign protein attacks or is attacked, a ferment is formed by the body cell and the invader is digested. The foreign protein is not a toxin, it is a cause of the formation of the antibody and consequently the cell is now in a state of anaphylaxis. In other words, the cell having been warned gets its ferment ready for the next invasion of a similar protein. If in the intervals there should be introduced other foreign material dissimilar in character the same prepared cell will not act, but other cells will become sensitized.

A toxin is always a protean. All these proteans contain a poisonous group that ordinarily proves

once been attacked, is forewarned and gathers reserve force in the shape of more ferment, and is ready for any future attacks. If these attacks come early and often each is disposed of gradually. On the other hand if there is an interval of several weeks there may be so much ferment stored up that the protein is overwhelmingly attacked and thus sets free the poisonous group of the molecule of foreign protein, often causing such disastrous results. Now to analyze further: All proteins contain a poison group but remain harmless until separated from their secondary groups and thus the intensity depends upon the thoroughness and probable rapidity of isolation. Foreign protein, as for instance taken from a forming thrombus, may not be infected with bacteria yet in its ultimate destruction cause a rise in temperature. This phenomenon is what I mean by protein fever.

How may we differentiate between protean digestion and sepsis? The patient's life may depend upon your action. Your attention is first attracted to the rising and falling temperature taken every

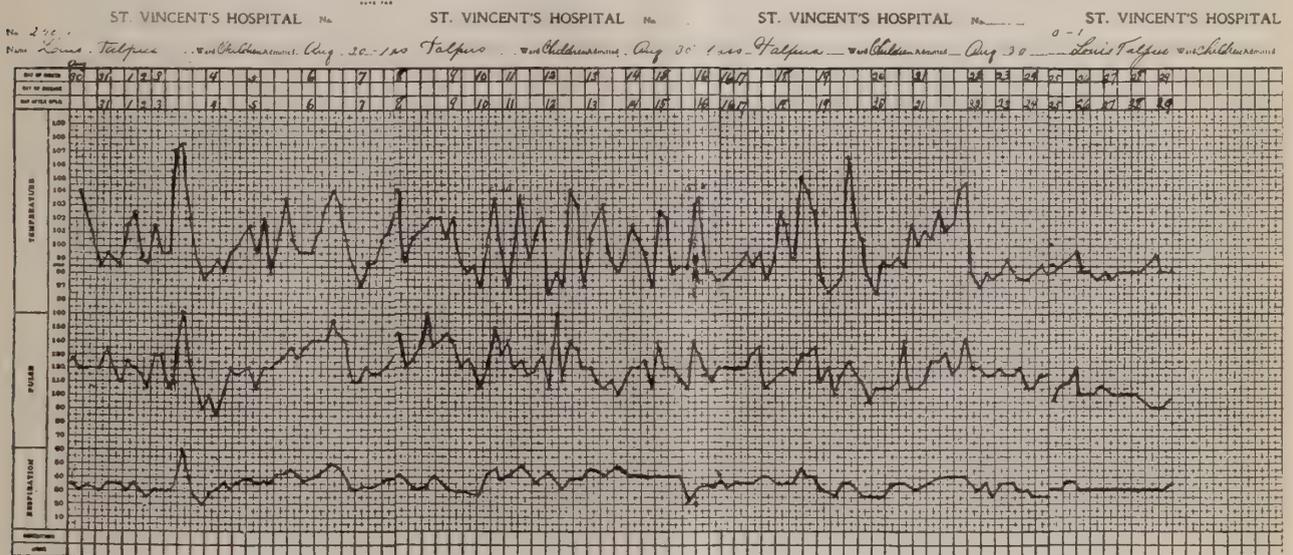

CHART V.—On September 3d, four days after the operation, the patient had a chill, and immediately afterward the temperature per axilla was 107.6°, pulse could not be positively counted, respiration 60. Had a consultation and decided to take blood cultures in an effort to determine whether the lateral sinus was involved. Agar, gelatin, and broth: cultures were negative. Took another blood culture September 10th, and it also proved negative. On September 19th the temperature rose to 106.6°; pulse 125, and respiration 35. Had another consultation and decided that, further blood cultures proving negative, we would not interfere with the patient, who, in his extremely precarious condition and pneumonic state, would not well stand the anesthetic nor operative investigation of the lateral sinus. Three days after this the temperature dropped from 104.4° to 98.6°, and has remained normal ever since, and the patient's convalescence was uninterrupted.

harmless. They may act as a virulent poison under certain conditions. Let us lead up to such a condition. A minute particle of the thrombus, which may be microscopical, is swept into the circulation. How small a particle is necessary cannot be stated. Many chemical poisons cannot be found with the microscope yet their symptoms are plainly manifest. It immediately becomes a foreign body and the circulating fluid must get rid of it, so it is brought within the sphere of the cell, which being stimulated to activity evolves a ferment and gradually digests the intruder. This process is always accompanied by heat and consequently there is a rise in temperature. As the process is completed the temperature falls again. This occurs after each successive invasion of the circulating fluid by a foreign protein. The cell now having become sensitized, or having

four hours. In protean fever besides the peculiar temperature there may be chills, sometimes severe, followed by perspiration, seldom headache. There is no pain in the mastoid region. The patient sleeps fairly well, feels well, has a good appetite, leucocytosis may be high. Some cases reported showed thirty thousand or forty thousand but usually ten thousand or twelve thousand only. The percentage of the mononuclear cells increases or the number remain stationary for a time and does not decrease. Sepsis also shows high and low temperature with severe rigors and sweating and anorexia. The patient sleeps badly, and there is an increasing depression. These symptoms gradually grow worse to dissolution. The blood count is helpful in both cases; in sepsis look for bacteremia, rising leucocytosis with increased polynuclear per-

centage and a falling percentage of mononuclear cells. When hemolytic streptococci are found, the case must always be treated energetically. A deceptive class of cases is that following some kind of epidemic, like the so-called influenza. For instance, patients may go on with mild symptoms for several weeks and possibly end disastrously but in these cases pain over the mastoid is always present and always deep seated. The temperature seldom runs very high, but these cases are treacherous. However, the blood picture will usually tell the story.

There are many case reports appearing in literature in which a tentative diagnosis is made of sinus thrombosis with recovery because they do not show a septic chart. A thrombus does not necessarily mean danger whether it is in the cranial sinuses or other veins in the body. This may be noticed in many cases of thrombophlebitis in the lower limbs; if all sinuses were opened postmortem we might be surprised to find thrombi that were never suspected. We remove a thrombus because it is septic, never because it is present. A septic thrombosis is often rapidly fatal, even when removed early. Sepsis is often profound and it may take the patient weeks to recover. A slow forming thrombus gives a far more favorable prognosis, especially if the temperature does not reach 105° or 106° F. repeatedly. I have never found these to be fatal when a remission lasted over twenty four hours. My experience has been with suppurating otitis only, and therefore cannot be equally positive in zymotic diseases. (In endocarditis a similar temperature may occur.)

A case reported by Dr. Alter, of Toledo, seems to be fairly typical of protein digestion. Alter states, in summing up, "we abstained from further interference, being well aware of the fact that had this been a case of sinus thrombosis we would very likely have lost our patient."

The doctor unfortunately assumes that all cases of sinus thrombosis are fatal while the fact remains that only in septic cases do the patients fail to recover.

I believe it is quite common to regard sinus thrombosis in otology as extremely dangerous. My object in this paper is not to regard it lightly but to call attention to the many patients who recover without further operative interference and give a possible explanation of the prominent symptoms.

1001 MAIN STREET.

Clinical Signs of Cancer of the Esophagus.—Guisez (*Presse médicale*, May 5, 1920), on the basis of cases subjected to esophagoscopy and subsequently kept under observation, lays stress on certain clinical signs, viz., frequently very insidious onset, selective dysphagia as regards bread and meats, preservation of the appetite to an advanced stage, expectoration of small amounts of blood-stained mucus, malodorous breath, and a white coating at the base of the tongue. Differentiation from inflammatory strictures and pseudocancers is sometimes difficult; in this event esophagoscopy settles the diagnosis.

LONDON LETTER.

(From our own correspondent.)

Aid for Tuberculous Women.—British Hospital Closes.—Cause and Treatment of Visceroplithis.—More Medical Students in Great Britain.

LONDON, June 6, 1920.

The committee of medical men appointed by the Minister of Health to advise his department in reference to tuberculous diseases have during the past two months been engaged in the selection of sites for the ten village settlements which are to be established in Great Britain for ex-service men. The committee are able to report great progress, as they have settled upon six sites out of the eight to be allotted in England. These are in Norfolk, Cambridgeshire, Essex, Kent, Yorkshire, and Cheshire. One settlement is to be provided in Wales and another in Scotland; and it is probable that an eleventh will be established in Ireland.

It was pointed out recently in the *Daily Telegraph* that while the various training colonies and industrial centres for tuberculous ex-soldiers and ex-sailors are still developing, and likely to be of great help to the men, no provision has been made for women suffering from tuberculosis, of whom there are many in England who are obliged to work for a living, and yet, on account of their health, are unable to work in towns. It is suggested that the State provide institutions or sanatoriums in which these women can work at various industries and earn enough to support themselves. Attention is drawn to the fact that so frequently one sees young women just commencing a career smitten with tuberculosis. They have sanatorium treatment for about three months and are then told that they must on no account go back to their former employment if they wish to keep well. They are faced with the difficulty of learning a new occupation and finding ideal conditions of labor, generally a sheer impossibility. Some are fortunate enough to have people on whom they can depend, others go from one sanatorium to another costing the State at least two guineas a week; others again leave the sanatorium to take up some work, but have to return in the course of a few months for further treatment. If an institution could be provided where the stronger subjects could live under ideal conditions, and thus continue their treatment, they could work at one or another of the occupations provided, and at least help to earn their board and lodging. If, in addition to providing the institution and bearing the initial cost, the State were prepared to offer a small wage to each worker, possibly repayable from the sale of her work, it would enable the women to provide themselves with clothing and, to some extent, free their mind from worry. It is urged that all the women should be insured under the National Health Insurance Act, so that if they break down and draw sick benefit they will be treated in the same way as the men.

* * *

An illustration of the financial stress of British hospitals was afforded recently by the announcement of the decision to close the inpatient department of the National Hospital for the Paralyzed and Epileptic, Queen's Square, Bloomsbury, Lon-

don. It was stated some little time ago that the hospital was sadly lacking in funds, but it was hoped that in view of the reputation of the institution and the splendid work it was doing and had done, an appeal to the generosity of the public might have the result of raising sufficient money to tide over the existing difficulties. However, the aid has not been forthcoming, and there is no alternative but to curtail expenses in every possible way. The greatly increased cost of living has weighed heavily on all charitable institutions. The expenditure of the hospital in question has risen during the past five years from £16,000 to £32,000 on which an annual deficit of £7,000 has been incurred, and, as said before, the committee have come to the conclusion that the only course left is to close the wards. The outpatient department will remain open, but no more patients will be admitted for treatment, and a long waiting list has been cancelled. Dr. Addison, the minister of health, stated in the House of Commons a few days ago that he had been given to understand that the King Edward Hospital Fund was prepared to consider the application from the hospital for an immediate emergency grant.

* * *

At a meeting of the Edinburgh Medico-Chirurgical Society, held on June 2d, enteroptosis and associated conditions were discussed. Among those who took part in the discussion was Sir Harold Stiles, who said that of all the subjects in the borderland of medicine and surgery that of visceroptosis probably interested him most. In the majority of cases the patient had been treated by the physician, the gynecologist, and ear and throat specialist before coming to the surgeon. The surgeon, therefore, saw the late cases, but the important point was the origin of the condition. There must be an anatomical and developmental cause for the condition. The perfectly normal person, in the sense of the anatomist or sculptor, was the exception rather than the rule; but within certain limits of variation many persons might be regarded as normal, and there might be considerable departures from this and yet no symptoms might arise. There were often physical defects which, in the first instance, did not lead to disease. There were variations in the skeleton, and the long and slender type supplied the cases of visceroptosis. In certain families it was not difficult to understand from the configuration why there might be displacements of the stomach, kidney, ovary, colon, or uterus. Diversity must be expected in the number and position of folds, because of the complexity of development of the intestine and peritoneum. Certain children were born with a degree of visceroptosis, and it was only a question of time before symptoms would arise. The proximal part of the colon, because of the way in which it was slung and because of its greater absorptive function, gave rise to symptoms much more readily than the distal part. The formation of various bands was described. The absorption of toxins led to faulty muscular tone, involving both voluntary and involuntary muscle. Innervation was interfered with, adipose tissue was lost,

and the viscera tended to slip downward. An essential in treatment was physical education, and if this was carried out in children of predisposing type, the visceral and associated clinical conditions would not occur. Enteroptosis affected more women than men. It was more common among the unmarried and the married without children, and it was possible that there was a subtle something, perhaps of a sexual character, which determined the onset of symptoms. In bad cases a plaster cast should be taken and supports made from it. Exercises were essential. In the neurasthenic patients, presenting severe symptoms, removal of the proximal part of the colon was of benefit in carefully selected cases. Sir Harold Stiles said that he had done the operation in sixty cases. He had been able to follow twenty-seven, and in a third of these there had been great improvement, in one third some improvement, and only in two cases had there been no benefit. Mr. Dowden agreed with him that symptoms often did not arise until what he also has noted as a "subtle something" had occurred. This was sometimes a mental shock or worry. Dr. Edwin Bramwell said that emotional conditions often determined the onset of symptoms, and referred to the danger of setting up an anxiety neurosis by the search for an insistence on a physical cause for symptoms. Perhaps, after all, visceroptosis is more of a neurosis than due to physical causes, or is it the physical cause with its attendant or subsequent toxemia that brings about the neurosis? Sir Arbuthnot Lane insists that the neurosis is the effect and not the cause of visceroptosis, and his opinion carries great weight.

* * *

At a recent meeting of the General Medical Council, Sir Donald MacAlister, the president, said that while on the home list only 872 practitioners were registered in 1919, no fewer than 450 were registered in the Colonial and foreign list. The result was that the total number of new names was higher than in any year since 1915. The proportion of woman practitioners had increased and was likely to increase during the next year or two. It was said, however, on good authority, that their services were in less demand than during the war, and that newly qualified women were finding difficulty in obtaining suitable opportunities for professional work. Supply and demand would no doubt adjust themselves in time but in view of the large entry of woman students it was proper to warn those concerned that in the meantime individual disappointments might be encountered. The Medical Students' Register indicated that the depletion of their professional ranks by the wastage of war would in a few years be much more than made good by the addition of newly qualified men. No fewer than 3,420 medical students, men and women, were registered in 1919, as compared with 1,600 in 1914. The number of registrations exceeded by over 1,000 the highest previously recorded, namely 2,405 in 1891. The strain thrown upon the medical schools of the country was for the time excessive, and most of the schools would welcome an ebb in the tide of applican^{ts}.

tation through the mail as second class matter.

NEW YORK, SATURDAY, SEPTEMBER 4, 1920.

PHYSICIAN AUTHORS—DR. OLIVER
WENDELL HOLMES.

America's greatest physician author, Dr. Oliver Wendell Holmes, was a gentleman and scholar of the old school whose poems and essays stand high among the classics of the literature of this country. He was a novelist, too, but his fame as a novelist proved to be somewhat ephemeral. Nevertheless, his *Elsie Venner* was the most lauded novel written in America during the decade of 1860-70. "Medicated fiction" Dr. Holmes called it, chatty, discursive and brilliant, but hardly a novel in the strict sense of the word. Elsie is a mere case of antenatal impression. The plot is what the critics are wont to call extravagant and unconvincing. Sad to say, a vast majority of fiction plots are of that very calibre. But Dr. Holmes's object in the writing of *Elsie Venner*, as he pointed out, "was to bring the dogma of inherited guilt and its consequences to a clearer point of view," and there is no gainsaying that this object was adequately achieved.

In *Elsie Venner* many subjects that are not germane to the story are discussed with the same brilliant wit and kindly humanity that characterize *The Autocrat of the Breakfast Table*, and its companions of the breakfast table series, *The Professor* and *The Poet*. It is on these three volumes, and especially on *The Autocrat* and *The Professor*, that the fame of Dr. Holmes chiefly rests. *The Autocrat* was the first. The first installment of it was published in the first issue of the *Atlantic Monthly* and leaped

into general popularity overnight. *The Autocrat* appeared in the first twelve numbers of the *Atlantic* and served to keep that new literary venture on its feet during the panic of 1857. The name *Atlantic*, incidentally, was Dr. Holmes's suggestion when he and the editor, James Russell Lowell, discussed a name for the new publication. Lowell had accepted the editorship of the magazine only on condition that he could have Dr. Holmes as his assistant.

The Autocrat papers were followed by *The Professor* papers, which rivalled the former in popularity. It was not until twelve years later that Dr. Holmes wrote *The Poet at the Breakfast Table*, but this series did not meet with the success that accompanied the earlier efforts. However, in all three there is a brilliancy of wit and humor that has seldom if ever been equalled.

In all Dr. Holmes wrote three volumes of poems and ten volumes of prose. Many of his poems were published while he was yet a student at Harvard, from which university he was graduated with the "famous class of '29." In obedience to the traditions of his mother's family, Dr. Holmes, following his graduation from Harvard, began the study of law, but he found law uncongenial and after a year gave it up and turned his attention to the study of medicine, and soon found that he liked it. Meanwhile he dabbled in literature and it was at this time that he wrote those fervent verses, *Old Ironsides*, which saved the historic frigate *Constitution* from destruction. *Old Ironsides* was what Dr. Holmes called "an impromptu outburst of feeling" inspired by a Navy Department order that the *Constitution* be destroyed. The verses, still popular, were sung all over the country and created such a weight of public opinion that the Navy Department had to countermand its order. Dr. Holmes's first volume of poems was published in 1836, and in it was his *Last Leaf*, accounted one of the finest pieces of poetry in the English language.

After a brief experience in medicine in Boston, Dr. Holmes went to Paris in 1833 and studied under many famous physicians and surgeons. He returned to Boston two years later and established himself there permanently, with this as his motto: "The smallest fevers thankfully received," as he put it humorously in conversation with friends. He already had a wide reputation as a brilliant wit and this seemed to cause the sober minded Bostonians to doubt his medical skill. Regardless of this skepticism of the Bostonians, Dr. Holmes was a very advanced physician who made many contributions to medical knowledge. In 1843 he published

an essay on *The Contagiousness of Puerperal Fever* and a fierce controversy arose over this publication, in which Dr. Holmes was assailed by those who disagreed with him. In time, however, he came to be honored as the discoverer of this truth. In his earlier years Dr. Holmes won many prizes for professional papers and eked out his income by lecturing on anatomy at Dartmouth College. His volume of medical essays, although not so well known to the general public as his other work, contains some of his most sparkling wit, his shrewdest observations and kindest humanity. In 1847 he was appointed professor of anatomy and physiology in the Harvard Medical School and continued this professorship until 1883, when he was seventy-four years old. From about 1860 onward this was about his only link with the profession, for following the publication of *The Autocrat* in book form he devoted himself wholly to literature.

As a writer Dr. Holmes was active almost up to the day of his death, in 1894, at the age of eighty-five. His third and last novel, *A Moral Antipathy*, was published when he was seventy-five and he wrote his *Life of Emerson* when he was past three score and ten. His last volume, *Over the Teacups*, after the manner of *The Autocrat*, was begun in 1888 when he was nearly four score. His place is among the bright and happy spirits of literature and there is fair assurance that he will forever hold that place.

THE DIAGNOSIS OF RETROVESICAL HYDATID CYSTS.

Retrovesical localizations of hydatid cysts in man are relatively rare. The cyst develops in the subperitoneal connective tissue between the bladder and rectum, and being supported by the pelvic floor the cyst grows to the sides of the pelvis and upward, compressing all the structures surrounding it. Usually its evolution is slow, but as soon as urinary disturbances accrue the consequences may quickly become fatal. The rounded shape of the growth, its situation in the midline and the fluctuation frequently lead to the diagnosis of an over-distended bladder, as its upper outline may reach the umbilicus. Passage of a catheter shows that the bladder is empty or at least contains an ordinary amount of urine and the tumor will be found by rectal examination, showing its pelvic development.

In Saxahausty's case the diagnosis of sarcoma of the prostate was made and after incision of the perineum hydatid cysts were seen to issue forth. Tillaux likewise made the same diagnostic error, while Wood performed a suprapubic cystotomy for what he supposed was a hypertrophied prostate. In

Kean's case—reported by Jendy (Thesis. Paris, 1913)—the patient was a boy of seven years; the diagnosis at first wavered between a cyst of the mesentery and a cold abscess developing in the horizontal branch of the pubis, the latter conclusion having been agreed upon. An exploratory puncture was consequently made and revealed the true nature of the tumor.

Usually the clinical diagnosis of these cysts is not made unless exploratory punctures or incisions are resorted to, but in some cases a correct diagnosis is possible without these means. The functional symptoms are not sufficient to make a diagnosis, although they may lead the surgeon to suspect the real condition of affairs, but the physical signs are all important. The tumor is hard, rounded, and smooth. These signs are constant and although they are not pathognomonic when met with singly, when they are all present in the case of a tumor of the pelvis they offer strong presumption in favor of a diagnosis of hydatid cyst. Unfortunately, the only truly pathognomonic sign—hydatid thrill—is absent and we only know of one instance in which it was present, that of Tuffier referred to by Getten in his thesis (Paris, 1898). When by puncture perfectly clear fluid is withdrawn the diagnosis can be made, but sometimes the fluid does not come away, although in these circumstances the possibility of a hydatid cyst must not be eliminated. When the needle does not give issue to the fluid it is because the cyst, filled by daughter vesicles, flees from the instrument just like the intestine in cases of ascites. If fluid does not exist or has become collected in the parts it cannot be withdrawn, as for example, in Legrand's case, where a cyst existed tightly packed with hydatids. Briefly, a diagnosis can be made if hydatid thrill can be made out or when the exploratory puncture is positive; it can only be one of probability when the physical signs exist. Research for the deviation of the complement and eosinophilia should be resorted to.

INTESTINAL VERTIGO.

Like the stomach, the intestine may be the cause of the phenomena of vertigo. Glenard, Sigaud, Vincent, not to mention others, have met with them in instances of prolapse of the transverse colon with bending of the angle, in distention of the colon by gas, and typhlectasis, while Pron, Mendel, and others have reported instances of vertigo in cases of chronic enterocolitis interspersed with acute painful paroxysms. Special credit is due to Loeper, of Paris, for the report of numerous cases with radioscopic verification, examination of the

blood pressure, etc., as well as the development of a brilliant pathogenic theory.

All types of vertigo may be met with in intestinal disturbances, from simple indecision in walking to the state of *mal vertigineux*, and even Ménière's vertigo with falling and vomiting has been known to occur. Loeper records the case of a male thirty-nine years of age who had been constipated for years and who complained of an emptiness in the head, cephalic malaise and fainting whenever he went two days without a stool. For several months the constipation had increased, likewise the other symptoms, to which an ataxic gait became added. He also suffered from beating in the head, tinnitus aurium and dizziness. All these symptoms disappeared after the intestine had been emptied by oil enemata. Abdominal palpation was negative, the appetite good and the general state perfect. The ears were absolutely normal, the pupils reacted to light although greatly dilated, and the patellar reflexes were exaggerated. Blood pressure was usually found below normal, the urine rich in indican.

Another case recorded by Loeper which we give as an example of intestinal vertigo was that of a male who had followed a farinaceous diet on account of a long standing enteritis. He suffered frequently from meteorism, pain, palpitation, nausea, tinnitus aurium, and vertigo and twice he fell although consciousness was not lost. Colonic distention was verified by radioscopy while the blood pressure reached twenty-one and more when the meteorism was marked and vertigo appeared. There were appreciable lesions of the circulatory system and by a less exclusive diet, combined with pancreatin, the blood pressure dropped to sixteen and the vertigo disappeared.

Intestinal vertigo in young subjects is not serious; it is a troublesome symptom but is usually recovered from by proper treatment. In elderly people, on account of the resulting high tension, it may be the prelude to cerebral hemorrhage. According to Loeper, the vertigo is due to a variation of pressure in the semicircular canals, which may or may not be independent of the general circulation. In the first case the blood pressure is normal or below normal and a spasm or localized flux comes into play; in the second case there is a sudden hypertension of the entire circulatory system.

All these phenomena may be provoked in patients with intestinal disturbances by four principal causes, namely: The congestion of the digestive apparatus during intestinal digestion; blood plethora; absorption of toxic products or at all events vasotonic substances, and, lastly, abdominal reflex. The hypotensive action of certain

toxic products elaborated in the intestine of constipated subjects and the passage into the urine of a hypotension of intestinal origin has been experimentally demonstrated by Loeper. Vertigo from hypertension is of reflex origin.

A NEW JOURNAL.

Decrease of working hours must bring increased leisure for reading of all the marvels around us. Some, of course, are satisfied with a jerky article in the Sunday paper, or the report of a discovery, condensed to absurdity, in the daily news. In *Discovery*, which is a popular journal of knowledge, published by Murray in London, the opinion is given that the specialist, when he has told of his results to fellow workers in the usual way, should make those same results plain to the ordinary man in books, pamphlets or articles. Certainly, those papers in the first number are extraordinarily clear and well chosen, but this was to be expected, for all the leaders in science—including medicine, surgery and pathology—are on the writing staff. The journal is maintained under a deed of trust; the Presidents of the Royal Society and the British Academy being two of the trustees, and the British Psychological Society and the Royal Society of Economics on the committee of management, along with every learned society of note. Its good paper and large print are not minor virtues in these days of expensive light and efforts to read during the daily ride on rail and road.

News Items.

Mount Sinai Hospital Receives Gift.—The late Henry L. Einstein, of New York, bequeathed \$25,000 to Mount Sinai Hospital.

Additions to University of Maryland Hospital.—The University of Maryland Hospital is undertaking to raise funds to provide an obstetrical department and a nurses' home.

Prize for Ambidexterity.—The Medical School of Guayaquil, Ecuador, has offered a prize of 100 piastres to the schoolmaster who trains the largest number of ambidextrous pupils.

Plague at Galveston.—The eighth case of bubonic plague is reported at Galveston by surgeons of the United States Public Health Service, and another case is under observation.

Death of Professor Guyon.—Jean Casimir Félix Guyon, word of whose death has recently been received, was professor of genitourinary surgery at the Hôpital Necker, Paris, and for many years editor with Lancereaux of *Annales des maladies des organes génito-urinaires*. He was a member of the Institute and of the Academy of Medicine.

Radium Service at Hôtel-Dieu.—The municipal council of Paris has decided to add to the Hôtel-Dieu a radiotherapeutic department for the treatment of cancer. A gift of 40,000 francs has been offered by the *Ligue franco-anglo-américaine*, and the remainder of the cost will be defrayed by the municipality.

Dysentery in Baltimore.—An unusually large amount of dysentery has been reported during the present summer in Baltimore, and the infant death rate has been increasing.

Chicago Polyclinic to Build.—The Chicago Polyclinic is endeavoring to raise funds for a hospital building, to be erected on a site adjoining the present Henrotin Hospital.

Harvard Medical School Receives Gift.—The Rockefeller Foundation has given the Harvard Medical School \$350,000 for the development of psychiatry and \$300,000 for the teaching of obstetrics.

Canadian Anesthetists Form Society.—The Canadian Society of Anesthetists was recently formed, with the object of promoting the science, practice, and teaching of anesthesia. Dr. Samuel Johnston, of Toronto, is president.

Physical Education in France.—A bill providing for compulsory physical education of children has been passed by the French Senate. The training will begin at the age of six and in the case of boys will continue until their period of military training.

Alcoholic Cases Increasing at Bellevue.—A report of Commissioner of Charities Bird S. Coler states that cases of alcoholism at Bellevue Hospital have increased in frequency during the last few weeks until the number virtually equals that before prohibition.

Dr. Huffman Receives Appointment.—Dr. Otto V. Huffman, formerly dean and acting provost of Long Island College Hospital, has been appointed a member of the faculty of the New York Post-Graduate College and Hospital and chief of the medical clinic.

Resignation of Dr. Hyman.—Dr. Albert S. Hyman, resident physician at the Long Island Hospital, has resigned to become superintendent of the Mt. Sinai Hospital in Philadelphia. His successor is Dr. Albert B. Murphy, formerly assistant resident physician at the hospital.

Kings County Almshouse to Be a Hospital.—The Kings County Almshouse, N. Y., has been closed and will be turned into a hospital for chronic cases, to be administered by the city. About 600 chronic cases will be transferred to the new institution from the Kings County Hospital.

Personal.—Dr. L. Duncan Bulkley, of 10 East Sixty-first Street, New York, has retired from the active practice of dermatology and will devote his attention to consultation practice in the same and to the treatment of cancer.

Dr. Harry Plotz, of the U. S. Public Health Service, has recently returned to this country from Poland.

Honorary Degrees.—The University of St. Andrews has awarded the degree of LL.D. to the following men: Mr. W. J. Matheson, president of the biological laboratory of the Brooklyn Institute and chemical adviser to the New York City Board of Health; Dr. Leon Frederick, professor of pathology in the University of Liege, Belgium, and Dr. Norman Walker, inspector of anatomy for Scotland and representative of the profession in Scotland on the General Medical Council.

Interallied Conference.—The fourth interallied conference for the study of questions pertaining to war invalids will be held September 19th to 24th in Brussels.

New Westchester Hospital.—A new hospital to be known as the Valhalla Neurological Hospital will be opened October 1st at Valhalla, Westchester County, N. Y. The institution will be located on a site covering twenty-five acres and include a tennis court and athletic grounds. There are eighteen buildings. Among those on the medical executive committee are: Dr. Max G. Schlapp, professor of neuropathology at New York Post-Graduate Medical School and Hospital; Dr. John P. Grant, Dr. John J. McPhee, Dr. Emil Altman, Dr. W. I. Sirovich and Dr. Julius Broder.

Regional Health Conference in Washington.—The first of a series of regional health conferences authorized by the International Health Conference in Cannes is to be held in Washington, D. C., December 6th to 13th. It will be devoted to a consideration of venereal disease.

The conference is being organized under the joint auspices of the United States Interdepartmental Social Hygiene Board, the United States Public Health Service, the American Red Cross, and the American Social Hygiene Association. Professor William H. Welch of Johns Hopkins will serve as president.

The conference will review past experiences and existing knowledge as to the causes, treatment, and prevention of venereal diseases, and will formulate recommendations relating to a practicable three year program for each of the North and South American countries participating. In addition it will make suggestions for putting such programs into effect.

Died.

BOONE.—In Troutville, Va., on Friday, July 9th, Dr. George A. Boone, aged seventy years.

CHURCHILL.—In New York, N. Y., on Friday, August 20th, Dr. Frank Churchill, aged sixty-six years.

CLASSEN.—In Albany, N. Y., on Thursday, August 12th, Dr. Frederick Luke Classen, aged sixty-three years.

CRACRAFT.—In Wheeling, W. Va., on Monday, July 26th, Dr. William A. Cracraft, aged seventy-six years.

FLORENCE.—In New York, N. Y., on Sunday, August 8th, Dr. William Steed Florence, aged twenty-three years.

FURNESS.—In Wallingford, Pa., on Wednesday, August 11th, Dr. William Henry Furness, aged fifty-four years.

GELNEAU.—In Easthampton, Mass., on Wednesday, August 18th, Dr. Joseph Homer Gelineau, aged thirty-eight years.

HARRISON.—In Enfield, N. C., on Thursday, August 19th, Dr. Aristides Smith Harrison, aged fifty-six years.

LAASE.—In New York, N. Y., on Saturday, August 21st, Dr. Christian Frederick John Laase, aged fifty-one years.

MCDOWELL.—In Butternut, Va., on Thursday, July 29th, Dr. Ivan W. McDowell, of Savannah, Ga., aged thirty-five years.

MURPHY.—In Elmira, N. Y., on Tuesday, August 7th, Dr. Daniel P. Murphy, aged forty-six years.

WAGNER.—In Warrensburg, N. Y., on Sunday, August 8th, Dr. Edward Wagner, aged fifty-one years.

WESSELHOEFT.—In Cambridge, Mass., on Tuesday, August 17th, Dr. Walter Wesselhoeft, aged eighty-two years.

Book Reviews

PRINCIPLES OF ANTENATAL AND POST-NATAL PHYSIOLOGY.

The Principles of Antenatal and Postnatal Child Physiology, Pure and Applied. By W. M. FELDMAN, M.B., B.S. (Lond.), Assistant Physician and Lecturer on Child Physiology at the Infants' Hospital. Illustrated. London and New York: Longmans, Green & Co., 1920. Pp. xvii-691.

This is a comprehensive study of the physiology of the fetus and child. Too little has been offered in this field, but now we are rewarded by a splendid textbook that may be said to be a solid foundation for further building. Perhaps our studies of physiology originated from a curious introspection similar to that revealed in the life of Leonardo da Vinci and we did not readily realize the importance of the study of the infant and fetus. Here, indeed, if we are to build a rational structure, should the beginning be made. Another reason for lack of study in this domain has been the lack of financial remuneration in treating an unborn fetus. It would seem that at best the study was an abstract one. But this is not true, for a comprehensive understanding of the underlying dynamics would clarify many of the obscure phenomena encountered in later life.

Until recent years pediatrics was not considered a special subject. Jacobi, in this country, was one of the pioneers who gave pediatrics a separate place in the world of medicine. At present we are aware that the physiology of childhood differs from that of adult life. The pathological conditions are different. The bodily proportions, and bodily changes in growth and nutrition are not the same. Then we also have the transitory stages at the time of birth and during the period of adolescence. During these times vast physiological changes occur. As physicians it is our duty to try and know more about them. In Feldman's book many of these processes are described, among them some to which we have given little consideration in the past.

Heredity and the germinal stages are considered, as well as the physiology of conception. A broad working concept of heredity is presented. This is then followed by the postconceptional or intrauterine stage. Of vital importance are the chapters on general physiology, metabolism, and the mechanics of development. New light is shed upon fetal secretions, excretions, and the biodynamics of growth. The physiology of pregnancy is discussed in detail, and this portion of the book should interest the obstetrician and gynecologist, for the concomitant changes in the maternal organs are also considered. Then comes a detailed and well presented account of the latest findings of the postnatal stage. The various systems are considered one by one and in their relation to one another. At no time does the author lose sight of the organism as a whole. This, unfortunately, is a too frequent occurrence when laboratory workers attempt to present their findings. The special senses are taken up separately and are given the emphasis they require.

For the endocrinologist, there is a chapter devoted to the internal secretions. This is followed by an account of the changes during puberty and postnatal growth. The book is written in an interesting manner and this brief survey should show the many fields in which the book will be found of value.

AUTOEROTIC PHENOMENA.

Autoerotic Phenomena in Adolescence. An Analytical Study of the Physiology and Psychopathology of Onanism. By K. MENZIES. With a Foreword by ERNEST JONES, M.D. New York: Paul B. Hoeber, 1920.

This is a most valuable monograph. The subject of masturbation has usually been discussed with more reluctance than that of any other phase of sex. Menzies shows that not until Freud's analytical approach was it possible to give a correct interpretation to the general subject of autoerotic phenomena. Many ills of mankind have been attributed to masturbation, and men accredited with wisdom by virtue of their position or of degrees given them have spoken of masturbation as a vice. In the light of the new psychology, we are shown that autoerotic manifestations are phases of human development and not perversions. There are many erogenous zones besides the genitals and in early infancy these are made the region of autoerotic enjoyment. Thumb sucking, the retention of feces and urine, rubbing the thighs together, and many similar performances are all a part of the process. Much suffering and shame have been caused by the lack of knowledge surrounding this subject; neurotic symptoms are a common result of the fearful warnings and of the quack literature that has dealt with this subject in the past. We are now able to consider the autoerotic manifestations as one of the primary or infantile states in sexual development. Then comes the homosexual phase, which is finally supplanted by the heterosexual or complete love life. Menzies shows that masturbation continued over a long period is injurious inasmuch as it interferes with the appreciation of the normal sex life in later years. In women the zone of the clitoris predominates and it is only with difficulty that the transfer of the zone of excitation is made to the vagina. This accounts for the number of so-called anesthetic women. In the male the habit leads to premature ejaculation and does not allow for the full enjoyment of the normal sex act. This in turn is harmful to the female, for it does not permit her the degree of excitation necessary to produce an orgasm. This condition may lead to various neuroses, anxiety neurosis being a common sequel.

Max Hühner is quoted at some length. He believes masturbation to be caused mainly by an irritation of the deep urethra. This sounds plausible but is not true in the majority of cases. Hühner cites many cures which have been effected by massage and instillations of silver nitrate in the deep urethra. He may have found this condition in a number of patients, but surely he cannot logically believe that the great proportion of males who

masturbate have an irritation of the deep urethra. If he were to give the subject further consideration and observe the situation outside his treatment room, he would find that he was considering only a small number of masturbators. In order to understand the process in its entirety he would be obliged to accept the broader psychological concept of an evolutionary process in the development of the sexual cycle.

The monograph is an excellent one, for Menzies has quoted freely from Pfister, Freud, Jung, Hall, Jones, Ferenczi, Forel, and Havelock Ellis and has presented their views in an understanding fashion. In fact he has done little else but quote, but he has done it well. The book is timely and worthy of study.

A PSYCHOLOGICAL STUDY OF LIFE IN THE GHETTO.

Sarah and Her Daughter. By BERTHA PEARL. New York: Thomas Seltzer, 1920.

There is much of the sordid side of New York life in this book. The story, however, is lifted to the level of compelling interest by its truth and the fine appreciation of the individual struggle with which tragedy is met. To refuse to enter into such painful realism is to shirk the responsibility of its existence.

There are two sweeping forms of difficulty that lie at the bottom of the tragic experiences dragged through the lives of Sarah and the daughter. One is the economic maladjustment of society which permits of crushing pressure upon lives that ask merely free opportunity for themselves in their toil and in a modest selfdevelopment. Sarah and her family failed to find even such freedom to work until she was tempted to a misappropriated freedom in money making which again made slaves of herself and children. Poverty, sickness, dirt—these things were made to press their weight upon a spirit originally of too fine material to breathe beneath them. The only aid society was able or willing to render was to compress this already unbearable load under a falsely constructed protectiveness where individual expansion was the last thing to be conceived. It is an oft repeated tale, alas, this careless method of throwing an occasional sop to conditions fundamentally wrong. In this story Sarah and her daughter and all their associates are in one way or another victims of bad industrial conditions. Some of them achieve a victory of selfdevelopment which raises them above their original environment, but each one bears in one way or another the marks of social compression and attains a hampered success.

Below the broad economic basis for these individual histories is the profound psychology of the struggles which issue partially in defeat, partially in victory. Bertha Pearl's touch has the sureness of the artist who, while not always conscious of the psychological implications of her words, yet touches, however fleetingly, those ultimate sources which the clumsier scientist labors to define. The name of the book itself carries suggestiveness. The mother daughter theme here bears its own interpretation. Sarah's native refinement

is blunted by the duller religiosity of her inefficient husband and is pierced by reproach deeper than that of having been untrue to herself in the fact that she did not follow the true lover in the homeland. Such a nature with such a history is especially sensitive to the rivalry of a daughter like herself, whom she both loves and fears. The embittered woman possesses in Minnie a daughter of rare sweetness of character but of a greater sincerity than Sarah had been able to maintain. From Minnie's early childhood mother and daughter present a touching interplay of love. The mother depends upon the child's native tenderness and helpfulness and yet throws up that stubborn defense with which such natures shield their own deficiencies. The hatred of selfdefense and selfaccusation by the time the girl has reached puberty comes to separate hopelessly mother and daughter. The latter develops a brave endurance under hardship and temptation; the mother to the end is torn between blame to herself and perplexity over a need for independence in her child which she cannot quite define.

No less finely suggestive is the psychology that touches the other characters of the book. The story in its study of these struggles through a sordid environment and with underlying psychic burdens is so realistically human that one need not seek in it the register of either complete success or complete failure. Its review of social facts as well as of the human conflict in which the rich share with the poor should recall the reader to a double need. One cannot lay down the book as indifferent as before to the defects of our world with its hardest pressure upon such lives as these. Neither can one remain unappreciative of the necessity of deeper psychological knowledge. There are such sensitive souls as these on the East Side as on the West. The psychic maelstrom of hidden antagonisms and misunderstandings as well as of hidden powers sweeps beneath many such poignant situations as that of Sarah and her daughter. One must to a certain extent suffer with them in reading these pages. One will be rewarded, however, by finding two characters especially worth knowing. One may not pity them too much or find cause to blame, but one will love both Sarah and her daughter.

INDUSTRIAL PSYCHOLOGY.

Lectures on Industrial Psychology. By BERNARD MUSCIO, M.A. (Sydney); M.A. (Conville and Caius College, Cambridge); Late University Demonstrator in Experimental Psychology, Cambridge, etc. Second Edition, Revised. New York: E. P. Dutton & Co., 1920. (London: George Routledge & Sons, Ltd.) Pp. iv-300.

The intelligent young artisan, who reads such works as these much more than is imagined, is beginning to cast a suspicious eye on those learned men who want him to work in the position best fitted to his ability and to grant him all those recreationary periods which Nature has declared necessary for sagging nerves and the mischief wrought by noise and the ghastly monotony of repetition. Is it, he asks, that he may know the gorgeousness of life, may conquer the daily task himself unconquered? Or has the economy of mercy been discovered, have the future returns of scientific management been seen as more profitable than the

immediate ones of continuous work at high pressure?

Then again, in his irrational way, he asks what will be done with the incompetent whom it will take a long, long time to convince that the new is the best, who is wholly bent on contesting each inch of ground with the insistent monster, machinery? Is it not possible that a few competent may do the work of many stunted in mind and body and the question of employment prove a tougher one than ever for philanthropists and employers? Labor saving, energy saving must be translated into the workman's own language. Our next step must be to prove that all the gain will not be on the employer's side, nor behind the apparent relief from hard labor will there lie ambushed the same old enemies of want and sickness and old age. A feeling of fear, leading to hostility, has come. "Organized labor has declared that scientific management is essentially autocratic, a reversion to industrial autocracy which forces the workers to depend on the employer's conception of fairness and justice, and limits the democratic safeguards of the workers."

Now for an absolutely fair discussion of what psychology can do in the labor world, of what it can do in the way of obviating accidents to the public and to workmen, of increasing the amount of work while diminishing fatigue and time taken, it would be difficult to find a wiser volume than this, for no point is too small to discuss and elucidate when it will lead to a clearer understanding of all that seems so obvious to us, so entangled to the working man.

THE WORK OF THE RED CROSS.

The American Red Cross in the Great War. By HENRY P. DAVISON, Chairman of the War Council of the American Red Cross. Illustrated. New York: The Macmillan Company, 1920. Pp. i-302.

It is so often thought that everyone knows about the Red Cross, that no one thinks it worth while to let anyone know how things began. Who knows that the American National Red Cross was permanently incorporated in 1905 with the President as president? Who knows of the eager, tempestuous giving which formed its early share in the war, or the generous help given the troops on the Mexican border, where 75,000 men rehearsed the drama and learnt a few of the hardships awaiting them overseas?

The author has wisely kept the work in each country separate, for this is a work of reference, not merely a collection of anecdotes or things remembered, and the last chapter reminds us that the Red Cross, now figuring as a section of the League of Red Cross Societies, founded May 5, 1919, is toiling away at the weary task of clearing up after the war. The still greater task awaits it of promoting the welfare of mankind by furnishing the medium for bringing within the reach of all peoples the benefits to be derived from present known facts and new contributions to science and medical knowledge and their application, and to coordinate relief work in case of great national or international calamities.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

RELIGION AND THE NEW PSYCHOLOGY. A Psychoanalytic Study of Religion. By WALTER SAMUEL SWISHER, B.D. Boston: Marshall Jones Company, 1920. Pp. xv-261.

REPORT FOR THE YEAR 1919 OF THE CANTON HOSPITAL. Canton, China: Canton Medical Missionary Society and the Canton Medical Missionary. Pp. v-120.

BIBLICAL STUDIES. Moses the Founder of Preventive Medicine. By PERCIVAL WOOD, M. R. C. S., L. R. C. P., Captain, R. A. M. C., Author of *The Whole Duty of the Regimental Medical Officer*. New York: The Macmillan Company, 1920. (London: Society for Promoting Christian Knowledge.) Pp. xi-116.

TUBERCULOSIS AND PUBLIC HEALTH. By H. HYSLOP THOMSON, M. D., D. P. H., County Medical Officer of Health, County Tuberculosis Officer and School Medical Officer for Hertfordshire; Formerly Tuberculosis Officer for Newport and East Monmouthshire, etc. New York and London: Longmans, Green & Co., 1920. Pp. xi-104.

AN EPITOME OF HYDROTHERAPY. For Physicians, Architects and Nurses. By SIMON BARUCH, M. D., LL. D., Consulting Physician to Knickerbocker and Montefiore Hospitals; Hydrotherapeutist to Sea View Hospital for Tuberculosis, etc. Illustrated. Philadelphia and London: W. B. Saunders Company, 1920. Pp. ii-205.

MARINE HYGIENE AND SANITATION. A Manual for Ships' Surgeons and Port Health Officers. By GILBERT E. BROOKE, M. A. (Cantab.), L. R. C. P. (Edin.), D. P. H., F. R. G. S.; Chief Health Officer, Straits Settlements Medical Department; Port Health Officer, Singapore, etc. Illustrated. New York: William Wood & Co., 1920. Pp. ix-409.

THE SYMPATHETIC NERVOUS SYSTEM IN DISEASE. By W. LANGDON BROWN, M. A., M. D. (Cantab.), F. R. C. P. (Lond.), Physician with Charge of Outpatients, St. Bartholomew's Hospital; Physician to the Metropolitan Hospital, etc. Illustrated. London: Henry Frowde, Hodder & Stoughton, Ltd. (Oxford University Press), 1920. Pp. xi-161.

TREATMENT OF THE NEUROSES. By ERNEST JONES, M. D. (Lond.), M. R. C. P. (Lond.); President of the British Psychoanalytic Society; Member (for England and America) of the Council of the International Congress for Medical Psychology and Psychotherapy; Honorary Member of the American Psychopathological Association. New York: William Wood & Co., 1920. Pp. viii-233.

FUNCTIONAL NERVE DISEASE. An Epitome of War Experience for the Practitioner. Edited by H. CREIGHTON MILLER, M. A., M. D., Formerly Medical Officer in Charge Functional Cases, No. 21 General Hospital, Alexandria; Late Consulting Neurologist, Fourth London General Hospital. London: Henry Frowde, Hodder & Stoughton, Ltd., (Oxford University Press), 1920. Pp. xi-208.

SELF HEALTH AS A HABIT. By EUSTACE MILES, M. A., Formerly Scholar of King's College, and Honors Coach and Lecturer at Cambridge University; Assistant Master at Rugby School; Amateur Champion at Racquette and Tennis; Author of *How to Prepare Essays, How to Remember*, etc. Illustrated. New York: E. P. Dutton & Co., 1919. (London and Toronto: J. M. Dent & Sons, Ltd.) Pp. v-341.

A STUDY IN THE EPIDEMIOLOGY OF TUBERCULOSIS. With Especial Reference to Tuberculosis of the Tropics and of the Negro Race. By GEORGE E. BUSHNELL, Ph.D., M.D.; Colonel, United States Army Medical Corps (retired); Honorary Vice-President and Director National Tuberculosis Association of the United States; Member American Climatological and Clinical Association. Illustrated. New York: William Wood & Co., 1920. Pp. v-221.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Chronic Knee Strains.—H. Page Manck (*Virginia Medical Monthly*, April, 1920) comments on the frequency with which acute knee strains remain inadequately treated, chronic sensitiveness of the joint resulting. The joint should be fixed for four or five weeks, preferably on a posterior splint, so that after the first week daily massage of the thigh muscles can be practised. Exercises of these muscles, care being taken to allow no lateral motion, are very beneficial after the second week. Such treatment of the acute injuries would result in far fewer chronic traumatic knee joints. In the chronic cases the subjective symptoms are recurrent attacks of synovitis with or without locking, and the important objective symptoms, increased lateral mobility, tenderness over the injured ligament or cartilage, possibility of palpation of the cartilage in some cases, and atrophy of the muscles of the thigh. Of 159 cases collected by the author, of which only twenty-one apparently received any greater amount of treatment than rest and bandaging with or without local applications for a few days, 136 showed an atrophy of over half an inch of the thigh on the affected side. In cases with a history of repeated locking, operation for removal of a loose cartilage or loose body is indicated, with aftertreatment the same as in cases without locking. This treatment aims first at protection against recurrence, allowing the lateral ligament and synovia to recover and developing the supporting muscles. Effusion indicates rest in bed with snug bandaging until it has subsided. After this it is essential to prevent lateral mobility, an object secured by elevation of the shoe on the inner side and the application of a properly fitting brace, such as the Campbell knee brace or the knee cage devised by Robert Jones.

To prevent muscular atrophy and thus stabilize the joint there must be daily massage with systematic exercises, especially of the quadriceps; the latter is readily carried out by having the patient sit on a table with his legs hanging over the edge, simple flexion and extension bringing the muscles into play; a weight on the foot may be added. Bristow recommends graduated contractions of the thigh muscles with the Bristow coil. The elastic kneecap often prescribed in these cases is useless and even harmful in that it does not prevent lateral mobility but interferes with free use of the muscles. Cases with extreme lateral mobility require an operation on the internal lateral ligament, which is to be reinforced with the semimembranous or sartorius, as advised by McMurray. In cases with a bruised or hypertrophied infrapatellar pad the principal symptoms are recurrent synovitis with pain on complete extension and definite tenderness over the pad. Conservative treatment consists of fixation in slight flexion for a few weeks, followed by elevation of the heel of the shoe by one inch, which prevents pinching of the pad during locomotion. Good results have followed operative removal of the hypertrophied and bruised pad.

Ligation of the Common Carotid.—John Homans (*Annals of Surgery*, June, 1920) in describing a case of ligation of the carotid and in a review of the literature on the subject presents the following conclusions. If an injury to the common carotid is suspected, the patient should be studied with a view to determining the quality of the emergency collateral circulation; that the operator should consider the strength of the arterial circulation, as demonstrated by the blood pressure and the apparent degree of shock, or its absence; that he should not undertake the procedure in the absence of signs of dangerous extension of the local hematoma and in the absence of external hemorrhage, unless all the circumstances appear favorable for the resumption of a collateral cerebral circulation; that he should be prepared for the temporary or permanent repair of the common carotid in case temporary occlusion induces immediate cerebral symptoms; that he should ligate the jugular vein before or during occlusion of the artery; that he should be prepared to give blood transfusion to the patient; that he should use an anesthetic the least disturbing to the heart and to the brain—in other words, that local anesthesia should be used wherever possible; and that in case immediate operation is for any reason delayed, he may properly expect a greater likelihood of injury to adjacent nerves, but a far lower incidence of cerebral complications.

The Treatment of Empyema.—Evarts A. Graham (*Surgery, Gynecology and Obstetrics*, July, 1920) states that:

The extensive recent literature on empyema reveals both a striking tendency toward a more or less standardized treatment and a radical departure from methods in use prior to the war. The cardinal principles of, 1, the avoidance of an open pneumothorax during the acute pneumonic stage of the disease, 2, early sterilization and obliteration of the cavity, and 3, the maintenance of the nutrition of the patient, are discussed in this article. It is shown that the former prevalent conceptions of the mechanism of action of an open pneumothorax are incorrect.

In the normal thorax the mediastinal structures, instead of constituting a more or less rigid partition between the two pleural cavities, are in reality so mobile that to air pressure they offer a resistance which is equivalent to the pressure exerted by a column of water only one half centimetre to one centimetre high (.4 millimetre to .8 millimetre of mercury). This resistance is therefore negligible and from the point of pressure relationships, the thorax can be considered as one cavity instead of two. Any change of pressure, therefore, in one pleural cavity will manifest itself to practically the same degree in the other pleural cavity with the result that both lungs will be about equally compressed. The situation in this respect is the same in the dog as in the human, and, there-

fore, experimental results obtained on the dog can be directly applied to the human.

The likelihood of a fatal asphyxia as a result of an open pneumothorax depends upon a number of factors, important ones of which are the size of the opening and the vital capacity of the individual. A mathematical expression has been devised by which it is possible in a given case to approximate the maximum nonfatal opening in the chest wall if the vital capacity is known. One who has an average vital capacity and a normal thorax can withstand an opening in the thoracic wall of fifty-one square centimetres, but the individual of exceptional vital capacity can live with an opening of one hundred and one square centimetres. A bilateral open pneumothorax is practically no more dangerous to life than a unilateral opening provided that in each case the areas of the openings are the same. If the vital capacity is so low as to approximate the tidal air, even a very small opening may be fatal.

As shown in the text, these observations have a very important bearing on the question of open drainage of cases of empyema, particularly during the acute pneumonic stage when the vital capacity is low. After adhesions have formed and the mediastinum has become somewhat stabilized, both by adhesions and inflammatory induration, then the pressure relationships may be materially different on the two sides.

Effects of an open pneumothorax other than those directly upon the lungs are briefly considered, such as heat loss, changes in the systemic circulation and danger of infection. The value of Dakin's solution in sterilizing and obliterating empyemic cavities is shown, as well as its power to decorticate lungs. Collapsing thoracoplastic operations have the disadvantage, even when successful, of apparently permanently reducing the vital capacity. The maintenance of the nutrition of the patient is of fundamental importance.

Suprapubic Prostatectomy.—T. L. Deavor (*American Journal of Surgery*, July, 1920) mentions the following points in favor of suprapubic prostatectomy: The entire field is open to inspection, and within easy reach. Reflected light may be used. Rectal pressure elevates the prostatic region. In case of marked sepsis, it is the first step in a two stage operation. Complications, as hemorrhage, stone and prostatic bar, are more easily managed. The gland is just as accessible, and perhaps more so. Enucleation is very simple. The rectum may be as safely protected. No more damage need be done to the prostatic urethra, if due care is exercised. Drainage both ways is readily applied. Retrograde catheterization may be used, when it is impossible to reach the bladder by the ordinary way. A catheter may be fixed in position, to remain for the entire period of drainage. During the process of recovery, the wound is well placed for subsequent treatment away from the rectum, adding much to the comfort of the patient. Except in carcinoma, a fistula following this method is almost unknown. Should it occur, obliteration is always possible. The mortality should not be increased.

Röntgen Rays in Obscure Conditions.—George E. Pfahler (*International Journal of Surgery*, June, 1920) gives the following conclusions as to the uses of the x ray in diagnosis:

1. The röntgen rays are useful in the diagnosis of practically all obscure conditions in the body.

2. The organ involved is not always indicated by the character of the symptoms, and frequently an x ray study must include more than the organ to which the symptoms refer.

3. For accurate diagnosis it is essential that good röntgenograms be made, but much greater skill and a wider scope of knowledge are needed in their interpretation than in their making.

4. The purchase of an x ray outfit no more makes the röntgenologist than does the purchase of a set of surgical instruments make a surgeon.

Anesthetics in Shock.—McKean Cattell (*American Journal of Surgery*, July, 1920) gives the following summary of the experimental studies which were conducted on the effect of anesthetics in shock:

1. In the normal animal, ether, rapidly administered, causes a moderate fall in blood pressure, followed immediately by a recovery, so that by the time a degree of anesthetization is reached sufficient to cause a disappearance of the eye reflex, the pressure is normal. In shock the animal becomes very sensitive to ether, the same degree of anesthesia produced under exactly similar conditions resulting in a marked drop in blood pressure.

2. An increased sensitiveness to ether is brought about by any circumstances which tend to depress the general condition of the animal such as low blood pressure, hemorrhage, severe operation, or the injection of acid into the circulation.

3. In a shocked animal, sensitive to ether, nitrous oxide and oxygen may be given in the most favorable proportions, so as to produce the same degree of anesthesia produced by ether without causing a fall in blood pressure.

4. Experiments on the heart volume in intact cats, and on contractions of the isolated turtle heart, together with deductions from blood pressure, show that ether, from the very beginning of its administration, results in a depression of the heart and a decrease in its output, which is sufficient to account for the fall in pressure in both the normal and the shocked animal.

5. Large doses of adrenalin injected intravenously in shocked animals usually result in the disappearance of the sensitiveness to ether for a period of an hour or more. The evidence indicates that adrenalin acts on the heart in a manner which antagonizes the effects of ether. Pituitrin does not influence the pressure drop produced by ether in the shocked animal.

6. Determinations of leg volume with a plethysmograph, perfusion experiments, and results obtained from the injection of ether directly into the circulation, together with the form of the blood pressure curves, indicate that ether causes a contraction of the peripheral vessels in the normal animal. This constriction is caused, a, by a direct stimulation of the vasomotor centre and, b, by a reflex to the fall in pressure resulting from depression of the heart. In shock no evidence of a vasoconstriction produced

by ether was obtained, and pressor effects from asphyxia or sensory nerve stimulation become less or are entirely absent.

7. The cause of the greater depressing influence of ether on the blood pressure in shock is a disturbance of the vasomotor system. The usual compensatory constriction no longer occurs to offset the decreased output of the heart, so that there is no recovery of the blood pressure during the inhalation of ether, but instead, the pressure continues to fall. This might be due to a depression of the vasomotor centre or to an already existing maximum constriction, so that there would be no compensation.

Local Anesthesia in Rectal Surgery.—E. Jay Clemons (*Medical Council*, April, 1920) considers the postoperative advantages of quinine urea hydrochloride anesthesia in anorectal surgery to be as follows: First, being nontoxic there is no reaction. Second, as there is no interference with blood pressure there is no need to use drugs to block off absorption. Third, the drug being a mechanical irritant it causes the production of a plastic exudate which helps repair and prevents postoperative oozing. Fourth, this exudate having been thrown out and absorbed, a barrier is produced which enables the operator to get his patient on his feet while the repair is taking place. Fifth, there is produced a postoperative anesthesia for a week to ten days which is very grateful to the patient.

Cæsarean Section Under Local Anesthesia Combined with Morphine and Scopolamine Narcosis.—Frederick C. Irving (*Boston Medical and Surgical Journal*, June 3, 1920) says that Cæsarean section under local anesthesia combined with morphine and scopolamine narcosis is a useful and successful method of delivery in some of the graver complications of pregnancy. Among these are cardiac disease where one or more attacks of decompensation have occurred, diabetes, nephritis and cardiorenal disease, pulmonary tuberculosis, and bronchial asthma. In general it finds its application in those cases where we wish to avoid the pain and physical exertion of labor, the possible shock of an operative pelvic delivery, and the danger of a general anesthetic. Plenty of time must be allowed for both the general medication and the local anesthetic to act. Deliberate operating, with studious avoidance of roughness, is essential to success.

Benzylcarbinol as a Local Anesthetic.—A. M. Hjort and J. T. Eagan (*Journal of Pharmacology and Experimental Therapeutics*, November, 1919) describe an investigation of benzylcarbinol, or betaphenylethylol, also known as rose oil or orange oil. It is a volatile oil with a roselike odor occurring in nature in the volatile oils of roses, orange flowers, and pine needles. Its local anesthetic properties were studied by comparative tests with phenmethylol (benzyl alcohol) and with procaine (novocaine.) As determined by the wheel method, the local anesthetic power of rose oil seemed slightly superior to that of benzyl alcohol and procaine. It is more stable than benzyl alcohol. Its toxicity in white mice and the dog is about

the same as that of benzyl alcohol. One of the authors injected one mil of a one per cent. solution of rose oil subcutaneously in the volar surface of the forearm. The area became anesthetic to needle pricking for a period of five minutes. The solubility of rose oil is relatively low—about two per cent.—but is sufficient for its therapeutic use. It is cheaper, less toxic, and more stable than procaine. It is a commercial product found on the market regularly, being used in the manufacture of perfumes. It anesthetized the skin in a one fortieth per cent. solution in thirteen out of twenty-one cases.

Ethyl Chloride Anesthesia, Brief or Prolonged.—H. Abrand, (*Presse médicale*, May 5, 1920) recommends the use of Camus's mask for ethyl chloride anesthesia, but supplements it with a new device to permit precise regulation of the dose of anesthetic as well as the use of a single, graduated ethyl chloride ampoule of any desired size. No cooling device is required and the anesthesia may be begun with small amounts and later pushed as required. The patient, even if an inveterate alcoholic, goes under without any period of excitement and only rarely vomits upon awakening. Ethyl chloride anesthesia should be induced gradually to avoid choking sensations and possible acute toxic effects. Administration of small amounts may be repeated indefinitely, as the product is of relatively low toxicity and is quickly eliminated. Anesthesia should be obtained with a dose not exceeding one to three mils in children and three to five mils even in large adults. The anesthesia is maintained more and more easily as it is prolonged. The dose after induction in prolonged anesthesia is only about one half a mil a minute. Many extensive operations, such as arthrotomy, Estländer operations, arm and thigh amputations, and radical hernia operations, have been successfully performed under prolonged ethyl chloride anesthesia by the author and others. The anesthesia is not as deep as with chloroform, yet is wholly sufficient. The patients do not strain and radical cure of hernias is in no wise hindered. About eight to ten minutes after the induction the patient's face begins to perspire. The mask is then slightly raised to admit a little air. The color of the lips and ears is used as a guide. Not infrequently after ten to fifteen minutes the anesthetic may be completely suspended and the mask removed for a minute or two. At the first signs of returning consciousness, the patient is soon brought back into complete anesthesia. The final awakening is rapid and is at times attended with regurgitation of bile which, however, does not recur. The patient is always completely conscious when put back in his bed. One patient with an arm amputation wanted to walk back to bed.

Late Deaths from Chloroform in Liver Disease, Especially Cirrhosis of the Liver.—Fr. Brunner (*Schweizerische medizinische Wochenschrift*, June 17, 1920) urges a careful testing of the functions of the liver and kidneys by the usual methods before entering upon an operation on the biliary passages, especially when there is any suspicion that these functions have been diminished.

Miscellany from Home and Foreign Journals

Inflammations of the Nervous System.—Lewellys F. Barker, Ernest S. Cross, and Stewart V. Irwin (*American Journal of the Medical Sciences*, March, 1920) in discussing epidemic acute and subacute nonsuppurative inflammations of the nervous system prevalent in the United States in 1918-1919, encephalitis, encephalomyelitis, polyneuritis, and meningoencephalomyeloneuritis, state that the onset may be sudden or gradual, with or without prodromata. The most striking symptom, when present, is a drowsiness, which may vary in degree from apathy to coma. Some patients do not have this symptom. A patient may be drowsy in the day and wakeful and restless at night. Other disturbances include mental depression, anxiety, delirium, headache, vertigo, tachycardia and vomiting. Fever may or may not be present. A slight optic neuritis may occur, but choked disc was not seen.

Focal symptoms are motor rather than sensory. Commonest are bilateral nuclear and radicular paralyzes of the eye muscles, with ptosis and ophthalmoplegia externa et interna, but pontile and bulbar nuclear and radicular paralyzes, with facial paralysis, dysmasesis, dysphagia, or dysarthria, are common, as are symptoms that point to paralysis of part of the extrapyramidal motor system. The lesions that are most frequent as causes of motor focal symptoms must be located in the mid-brain about the aqueductus cerebri; the pons and upper medulla oblongata, and the basal ganglia. Less common are monoplegias, hemiplegias, diplegias, aphasias, contractures, choreatic and athetotic disturbances of motility and general or circumscribed convulsive seizures. Only in relatively few cases are there clinical signs of an outspoken meningeal irritation. The cerebrospinal fluid is clear and may or may not be under increased pressure. In the writer's experience, a cell count in the cerebrospinal fluid of from ten to one hundred small mononuclears along with a positive globulin reaction, with negative Wassermann, and negative bacteriological smears and cultures is, at the time of an epidemic of encephalitis, strong corroborative evidence of the disease in a patient in whom the process is for any other reason suspected to exist.

The blood usually presents a slight leucocytosis. A trace of albumin and a few casts are sometimes found in the urine, but the renal function appears to be unimpaired. Whether the disease terminates in death or in recovery, the course may be either brief or prolonged. In fulminant cases death may occur in a few days or hours. In many instances, both mild and severe, recovery has been rapid, the symptoms lasting from a few days to a month, but in the majority the disease is protracted, extending over several weeks or months. The prognosis as regards life is better than might have been expected. The mortality has varied in different countries and seems to have been greatest in Austria and France; in the series reported here there were no deaths. No definite statement can yet be made as to residues and sequelæ. The bacteriology of the disease is uncertain as yet. As regards treat-

ment the writers state that at the onset rest in bed, protection from external stimuli of all kinds, laxatives, bland diet, and relief of headache and pains, would seem to be desirable. In their experience lumbar puncture, done for diagnostic reasons, relieved the symptoms so markedly in several instances that it was repeated at intervals as a therapeutic measure. During convalescence, prolonged rest, careful nursing, a nutritious diet, and mild hydrotherapy, electrotherapy, and massage have been the only measures made use of. Complete recovery without residuals seems to be common.

Transmissibility of Lethargic Encephalitis.—A. Netter (*Bulletin de l'Académie de médecine*, April 27, 1920) reports a number of instances in which the source of infection in lethargic encephalitis could be definitely traced, and concludes that the disorder is certainly a transmissible disease, though the risk attending contact with such cases is relatively slight. The virus is probably carried in the salivary secretion. In view of the prolonged persistence of the virus in the nerve centres, the patient must retain for a long time the capacity to transmit the disease. Considerable evidence is at hand to the effect that encephalitis may be transmitted to another person by a convalescent. There is also reason for believing that the disease may be acquired through contact with a subject harboring an incomplete—fruste—or larval form of the disease, or even from a healthy person who has been in contact with a patient. All these considerations, some established and others merely probabilities, render advisable an attempt to detect and record all actual or suspected cases of the disease. Persons in contact with patients should be warned of the possibility of direct or indirect acquisition of the disease. Isolation of all patients is, however, difficult to secure at the present time.

Ocular Manifestations in Lethargic Encephalitis.—F. de Lapersonne (*Bulletin de l'Académie de médecine*, April 27, 1920) insists that ocular paralyzes are equally as important as somnolence from the standpoint of diagnosis. Frequently, however, the eye symptoms are difficult to detect, requiring a special ophthalmological examination. In patients confined to bed when first seen, the ocular paralyzes may have already disappeared—being fugacious and migratory—only to reappear a little later on; or, the seriousness of the general condition may not permit of the functional examination required for the detection of diplopia or paralysis of accommodation. Ambulatory patients nearly always consult ophthalmologists because of their eye disturbances, yet seldom reach the oculist when the disease is in its incipiency, the infection having been overlooked and the disorder ascribed to grippe or food intoxication. In some instances the infection has been duly recognized and treated, and the patients come because of visual disturbances persisting as sequelæ to the disease. Ptosis and sometimes diplopia are the most striking manifestations. Neuroretinal lesions have never as yet been ob-

served, save in cases of coincident syphilis and encephalitis. The oculomotor nerve is that most commonly affected, a special feature being that its involvement is of a fragmentary, partial type. A single muscle may be alone involved, and incompletely at that. Chauffard has laid stress on an incomplete unilateral or bilateral ptosis, only part of the cornea being covered. The patients do not attempt to react to the ptosis by throwing the head back or contracting the frontalis muscle. The internal rectus is often only incompletely involved and external strabismus is not always apparent, crossed diplopia resulting. Nystagmoid jerks rather than true nystagmus are present. At times limitation of vertical movements of the eye may be observed. In several instances the author noted unilateral internal ophthalmoplegia, evidenced by mydriasis and paralysis of accommodation. Complete or incomplete paralysis of accommodation, unilateral or bilateral, may likewise be present alone; this condition may strikingly reproduce certain paralyzes of accommodation witnessed after diphtheria or in botulism. The external oculomotor is more rarely involved, though the author has seen one apparent case of such involvement. No instance of independent paralysis of the patheticus has been reported. Apart from the manifestations due directly to nuclear or infranuclear involvement of the motor nerves there may also occur other forms of paralysis. One patient showed paralysis of convergence in spite of preservation of motor power in the two internal recti. Cantonnet saw a patient with conjugate deviation of the eyes. These cases show that the pathological lesions of encephalitis may involve the oculomotor pathways in their corticomesecephalic or supranuclear course.

Disturbances of the Reflexes in Lethargic Encephalitis.—G. Guillain (*Bulletin de l'Académie de médecine*, February 24, 1920) found the tendon reflexes greatly disturbed in three out of six well marked cases of lethargic encephalitis. The patellar, Achilles, mediopantar, posterior tibiofemoral and posterior peroneofemoral reflexes were all abolished in these patients. In the upper extremities, the stylo-radial, radiopronator, ulnopronator, flexor, biceps, and olecranon reflexes were likewise lost. In one of the other cases, dissociation of the tendon reflexes of adjacent spinal segments was noted. The right lower limb showed merely diminution of the patellar, Achilles, mediopantar, and posterior tibiofemoral reflexes, while the posterior peroneofemoral reflex was alone abolished. In the left lower limb, the latter reflex was likewise lost, but the other four were normal. In the upper extremities of the same patient the olecranon and stylo-radial reflexes were normal, but the radiopronator and ulnopronator reflexes were abolished. This dissociation of reflexes in a single limb is analogous to the frequently noted dissociation of eye paralyzes, as well as of the dissociation of the signs suggesting pyramidal tract involvement. The skin reflexes were normal in all the patients. The defensive or spinal automatic reflexes were never very marked. In no patient was there observed the contralateral

flexion reflex to pinching of the femoral quadriceps—a reflex frequently positive in acute meningeal reactions. Even where all the tendon reflexes in the extremities were abolished, the nasopalpebral or trigeminofacial reflex, resulting in closure of the lids upon percussion at the root of the nose, was preserved. In two cases the reaction of the pupils to light was sluggish, but not abolished. In two patients all tendon and skin reflexes remained unaffected, and both patients recovered. The reflex disturbances as a whole betoken diffuse involvement of the neuraxis in lethargic encephalitis, the lesions being therefore not limited to the bulbo-pontopeduncular region. The frequency of manifestations of cerebral excitation with mental confusion indicates also a participation of the cortex in the morbid process. Early abolition of reflexes seems to be of prognostic import; the four patients showing diffuse loss of reflexes all succumbing to the disease, while the other two recovered.

Trismus in Lethargic Encephalitis.—Audry and J. Froment (*Presse médicale*, May 5, 1920) report two cases of lethargic encephalitis attended with trismus but no other form of contracture. The first patient was a pregnant woman who succumbed early with ophthalmoplegia, dysarthria, polypnea, and disturbances of deglutition. The second was a farmer who, after a blow on the head, developed headache, dysarthria, masklike face, and prostration. Tetanus might have been thought of, but the paralysis of accommodation, few myoclonic contractions, and moderate somnolence suggested rather an epidemic encephalitis, a conclusion subsequently confirmed by the marked success which followed administration of injections of hexamethylenamine. In both these cases, as in the case reported by Chermite and Saint-Martin, the distinctly predominant involvement of the midbrain leads to the conclusion that the trismus was due to irritation of the motor nucleus of the fifth pair, in the absence, however, of any sign of involvement of the sensory portions of these nerves.

Intracranial Complications in Aural Suppuration Coupled with Syphilis.—E. J. Moure (*Bulletin de l'Académie de médecine*, May 11, 1920) states that while in most cases of intracranial complication in acute suppurative otitis media the symptomatology is sufficiently suggestive to permit of a proper diagnosis, in some cases the functional disturbances presented are so indefinite as to mislead the physician. Some patients with ear suppuration develop pain on the affected side, with swelling and tenderness of the mastoid. In addition to these customary indications of mastoiditis the patient is a little more prostrated than usual, sometimes presents bilateral spontaneous nystagmus upon lateral vision, has more or less disturbances of equilibration, and even at times a beginning Kernig. In short, in addition to the mastoiditis there are presented the appearances of an indefinite intracranial complication. If there is acute otitis media, antrotomy is practised or if the case is one of long standing otorrhea, the radical mastoid operation is done from the start. The wound heals as usual and the bone lesions are

recovered from, but the headache, nystagmus, disturbed equilibration, and Kernig persist and often become even more marked. At a second operation cerebrum and cerebellum are explored in vain with the needle, merely yielding in some instances clear cerebrospinal fluid under pressure which, upon laboratory examination, affords no special indication or points simply to a meningeal reaction of varying intensity. Nor is this second operation followed by any improvement. In such cases Moure thought of the possibility of complicating syphilitic manifestations. The Wassermann reaction usually confirmed this suspicion, being negative only once, and all the patients recovered under systematic antisyphilitic treatment. One, however, succumbed to a subsequent recurrence; the autopsy showed a gumma of the cerebellum undergoing softening, whence an acute meningitis which killed the patient.

Influenza in the United States Army.—Howard and Love (*Military Surgeon*, May, 1920) from a study of the reports of influenza in the army give the following conclusions:

1. Influenza prevailed much more extensively in the army in 1917 and during the early months of 1918 than has been commonly recognized. There were 40,512 cases of this disease reported in the army for the year 1917.

2. Unrecognized influenza was probably the primary and underlying cause of many of the atypical and fatal pneumonic infections occurring in the army camps during 1917 and the early months of 1918, in addition to the cases known to have been associated with measles.

3. Influenza in 1917 and the early months of 1918 was relatively mild in type as compared with the virulent type of the disease which appeared in army camps in September, 1918.

4. The extension of the virulent influenza from Camp Devens to other camps south and west in September, 1918, can be traced in many instances directly to the interchange of military personnel from infected to noninfected camps. The contagion was transferred by persons either themselves infected or who were carriers of the disease, and the extension followed ordinary lines of travel.

5. The height of the September outbreak of the disease in the United States extended over a period of about nine weeks (September 13 to November 15, 1918). During this period over 20,000 deaths occurred among troops in the United States alone in excess of the number that would have occurred if the disease death rate for the corresponding period of the preceding year had prevailed.

6. The height of the epidemic in France extended over the same period of time as in the United States.

7. Influenza and pneumonia were less prevalent and less fatal among our troops in France than in the United States.

8. The cantonment group of stations gave a much higher death rate from influenza and its complication than other groups.

9. For the entire army (approximately 3,500,000 men) there were 688,869 admissions charged to influenza for the year, or twenty per cent. of the command. This record does not represent the full incidence of the disease during this period.

10. There were 47,384 deaths from all diseases for the year 1918, of which 23,007 were attributed to influenza. In addition, 16,364 were due to pneumonic infections, bronchitis and pleurisy, many of which, it is certain, should have been charged to influenza, making a total of 39,371 due to acute respiratory diseases, or eighty-two per cent. of the total deaths from disease for the year. Influenza with its complications is charged with 48.5 per cent. of total deaths from disease for the year.

11. Influenza was more prevalent among white troops than among colored.

12. White soldiers from the south had much higher admission and death rates for influenza, pneumonia and other acute respiratory diseases than white soldiers from other sections. The lowest rates for these diseases were among white soldiers from the Pacific Coast and Rocky Mountain States.

13. The negroes stationed in the United States had lower admission rates than the whites for the country at large.

14. The incidence rate for all forms of pneumonia was nearly three times as high for the colored as for the whites for the entire country.

15. The death rate for all pneumonic infections was more than twice as high for colored troops as for whites.

16. The case mortality for all pneumonia infections for the colored was about twenty per cent. lower than for the whites.

A Contribution to the Study of Cerebellar Localizations.—Alfred Gordon (*Journal of Nervous and Mental Disease*, March, 1920) reviews the literature on cerebellar localizations and four case histories supporting Bolk's localizations. The author finds from these four cases that the function of certain muscular groups is affected in diseases of the cerebellum. The selectivity of affection indicates that the cerebellum possesses distinct centres for the extremities and for the head and trunk. These primary centres are composed of secondary centres controlling segments of limbs as to their stability and orientation. Clinical findings show that the cerebellar centres for the upper and lower extremities are located in the hemispheres on the homolateral side. The head, neck, and trunk are under the influence of the vermis.

A Consideration of the Nature of Auræ.—L. B. Alford (*Archives of Neurology and Psychiatry*, February, 1920) has attempted to point out anew the analogy between auræ and the hallucinations occurring in connection with sleep, hypnosis, crystal gazing, etc. According to this view, auræ should be regarded not as the result of discharges of an epileptic nature in some part of the cortex, but as deficiency reactions, like dreams, occurring when there is a disturbance of consciousness of a certain type. Their relation to the loss or disturbance of consciousness in epilepsy and migraine is assumed to be the same as that of dreams to drowsy or sleep states, and their content should be regarded as being determined by the same factors that determine the content of dreams and similar hallucinations which develop in connection with disease of the organs of special sense or of the nerves connecting them with the brain.

Proceedings of National and Local Societies

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

*One Hundred and Fourteenth Annual Meeting,
Held in New York, March 23 to 25, 1920.*

The President, Dr. CLAUDE C. LYTLE, of Geneva, in the
Chair.

(Continued from page 236)

SECTION IN SURGERY.

The Value of Position in the Operative Treatment of Hernia.—Dr. HENRY H. M. LYLE, of New York, with the aid of lantern slides, described the anatomical relationship of the abdominal and thigh muscles to Poupart's ligament and showed that when this ligament was relaxed the conjoined tendon would be relaxed. In operating for hernia he employed a simple procedure consisting of high ligation and transplantation of the cord, during which the patient was in the dorsal position. After putting in the first suture through the conjoined tendon, Gimbernat's ligament and out through the lower portion of Poupart's ligament, the patient's knees were propped up with the leg in internal rotation. The shoulders were also elevated. The hinged bed that had come into use during the war was useful in maintaining this relaxed position which was maintained for seven days and insured firm union.

Mesenteric Vascular Occlusion.—Dr. ROSS G. LOOP, of Elmira, said that this subject from the viewpoint of prognosis and treatment had received scant attention in our literature, and in the textbooks it was accorded little notice. In the French and German literature it had received much more complete discussion. Mesenteric vascular occlusion was not as rare a condition as was supposed and quite frequently it was mistaken for intestinal obstruction. He had seen seven proved cases within the last two years and was convinced that in the past he had failed to recognize many more. Its existence or nonexistence in obstruction cases spelled a bad or a good prognosis and influenced treatment. Mesenteric vascular occlusion presented two well defined forms. In the primary form the symptoms were not associated with other abdominal lesions. The process was one of thrombosis or embolism due to remote causes from the heart valves. Its practical interest lay in the fact that the surgeon might operate for the relief of intestinal obstruction, and at operation he had to deal with a self-reduced volvulus. If, on the other hand, a frank gangrene was found (a rare finding in early cases), he might resect the intestine without suspecting the cause of the condition. The second form occurred as a complication of various septic conditions and might be associated with the common forms of intestinal obstruction. As a complication of clean or aseptic surgery, it was responsible for many deaths that were attributed to postoperative ileus. The symptomatology in these cases was susceptible of another classification into fulminating and phlegmatic, both of which might be either primary or secondary. There might be considerable free fluid

in the abdominal cavity, ranging in color from a light yellowish to a dark brown. The blood vessels were cyanosed and dark. Gangrene might be present, or there might be mottled segments of intestine alternating with dark red ones. At times there might be small oval areas of necrosis. The peritoneum, except in areas where there might be local death, had not lost its glistening appearance. The involved coils were not distinct and lay inert and half filled with liquid, looking very much like a rubber glove with a little water in it. If handled the coils gave a peculiar sensation of weight and thickness. The mesentery was heavy and soggy, and thrombosed vessels might be seen if not obscured by tumefaction. One or two folds of the mesentery might hang down over the sacral promontory and give the impression of being adherent, but this was produced by the weight of the liquid contents. In all of his cases the middle third of the small intestine was involved and the mesentery appeared as a low attachment, and whether this had anything to do with the production of the condition he was unable to say. The fulminating cases presented a symptom complex which constituted a disease entity. The phlegmatic types were less easily recognized, especially if they were associated with preexisting trouble. The fulminating type was characterized by pain, sudden and violent, if primary, or if secondary by the same kind of pain in connection with the preexisting symptoms. The pain was worse on the left side. In the phlegmatic type the pain was not sudden or severe, but varied from a vague unrest to a severe cramp, and when this form was superimposed on another lesion it was insidious. Vomiting occurred in all the forms, was coincident with the pain, and tended to cease spontaneously in a few hours when the pressure above the lesion had been relieved by the vomiting. The muscle rigidity was not to be compared with that found in other equally severe conditions. The abdomen was not distended as in peritonitis. The condition was afebrile and the pulse soft and irregular. In the fulminating cases the patient was more or less in shock. Mesenteric vascular occlusion was a disease of adult life, more than seventy per cent. of the cases being in individuals over forty-five years of age. The condition might be mistaken for pancreatitis or rupture of a viscus. Moynihan stated that in this condition no surgeon could show a mortality of less than fifty per cent. The treatment was purely surgical, consisting of wide excision of the involved coils of intestinal anastomosis.

Special Points in the Surgery of the Gallbladder.—Dr. GEORGE W. CRILE, of Cleveland, Ohio, described the experience of his associates and himself in 1325 operations on the gallbladder and ducts from the viewpoint of the difficulties and failures that they had met with. Among the questions considered were how they might increase the certainty of relief, how they might decrease the risk from hemorrhage; what was the incision of choice,

and when the common duct should be drained. Hemorrhage might be met by transfusion. The best incision in operating on the common duct was parallel to the costal border; this did not divide many nerve fibres and secured against postoperative hernia. The incision should be long enough to insure adequate exposure. In cholecystostomy the best drainage was from the dependent point, and frequently this was obtained by a counter incision at the bottom of Morrison's pouch. In fulminating acute cases the only immediate procedure was to establish gallbladder drainage. It was very desirable to carry the acute gallbladder to the subacute stage before final operation. When this acute condition subsided and the patient's condition was stabilized, cholecystectomy was the procedure of choice in those cases giving a history of recurrent attacks of cholecystitis. In severe cases of acute cholecystitis he used a short incision, a round tube, plenty of gauze about the opening and no stitches.

The general principle of adequate exposure held for operations on the common duct as for those on the abdomen. In discussing cholecystectomy versus cholecystostomy, Doctor Crile said that in the absence of the gallbladder the common duct compensated by storing bile and this predisposed to the formation of stones and a recurrence of symptoms, so that the removal of the gallbladder was not without some unfavorable consequences. If the mucous membrane of the gallbladder was gangrenous, if the wall was thickened, or if stones were imbedded and after drainage there had been a recurrence of periodical attacks of cholecystitis with obstruction and infection, then cholecystectomy was indicated. If the gallbladder and cystic duct were normal, no matter what the size of the stone, there would rarely be a cycle of recurrent attacks and cholecystostomy would fulfill the requirements. In removing the gallbladder there should be free exposure through an ample incision so as to give free access to its base. The gallbladder should be dissected free by sharp dissection, without injury to the liver. The entire gallbladder should be freed from its attachments so that ample opportunity might be given for determining where it ended. The cystic duct should likewise be dissected free so that the exact point of division between the gallbladder and the cystic duct could be determined. The cystic duct should be taken off near the common duct. The clinical results following cholecystectomy were as much better than those following cholecystostomy as were those of nephrectomy better than those of nephrotomy. They were now doing about sixty cholecystectomies to forty cholecystostomies. In doing a cholecystectomy a careful dissection should be done so that the surgeon would not be at a disadvantage later if he were called upon to operate upon the common duct.

Liver shock was a common cause of death after gallbladder operations and was due to failure of the liver cells to perform their function. Its prevention was secured by the avoidance of liver cell depression. The depression of the liver cells was increased by trauma and by low blood pressure, and that meant suboxidation. To prevent this light gas anesthesia should be employed, the operation should

be as brief as was compatible with good surgery, blood transfusion should be given early, and heat should be applied over the whole abdomen.

Application of the Methods Developed during the War to the Fractures of Civil Life.—Dr. JOSEPH A. BLAKE, of New York, presented a lantern slide demonstration of the overhead suspension and traction treatment of fractures now being used in the treatment of fractures at Bellevue Hospital. At the beginning of the war they had treated fractures by the application of plaster of Paris, but they soon found that they would have to develop some method which would permit of better access to the wounds and which would be more susceptible of variation, so they came to use wire splints, and in 1917 and 1918 these were well established in the French and English armies. They were at first much hampered by the old opinions as to the treatment of fractures, namely, that these should be fixed as much as possible. However, the further they got away from the old idea of fixation the better were the results obtained. In fractures of the long bones it was easy to fix the distal fragment, but the difficulty came in fixing the upper or proximal fragment to the lower fragment.

The principles upon which the newer method was based was that when the proximal fragment was at physiological rest, it was in the position in which antagonistic muscles had brought it; it would not have much tendency to move in either direction, and if the upper fragment was in that position, the other fragment could be readily moved. Having placed the upper fragment in the position of physiological rest, the distal fragment was brought into line with it and then the whole extremity could be moved without moving the fracture. Doctor Blake then demonstrated the use of the overhead suspension frame in high fractures of the humerus. He said it gave uniformly good results, the only objection to it being that the patient had to remain in bed, and this was not an objection, considering the rapidity with which repair took place. He left the arm free during the day and put it back in the suspension apparatus at night, and in this way union was often obtained in eighteen or twenty days. In fractures of the forearm the fragments were not suspended in the same plane, one being suspended mesial to the other. In the application of traction they made use of the glued cotton glove with curtain rings sewed to each finger tip. This permitted of even traction, or traction might be applied to individual fingers. The Blake-Keller half ring thigh and leg splint was shown. This splint had proved of great value in the transportation of men with fractured femur, and with the Thomas arm splints should form a part of the equipment of every ambulance. He hoped that they would be able to extend some of these methods which had been so valuable in the treatment of fractures during the war to the treatment of industrial injuries of which there were at least three quarters of a million in this country every year. They shortened the period of convalescence and did away with at least five per cent. of the incapacity resulting from other methods.

MEDICAL MEN IN THE AMERICAN REVOLUTION.*

The New York Campaign of 1776.

By LOUIS C. DUNCAN, M. D.,

Washington, D. C.,

Lieutenant Colonel, Medical Corps, U. S. Army.

The siege of Boston had ended in March with complete success for the Colonists, a success to be followed by a long succession of dismal failures before victory would again cheer their hearts. Boston had been captured with little loss in battle casualties, and, what is even more surprising, with even less from sickness in the camps. This happy event was also not to be repeated; henceforth the army was to be dogged by disease, the camps to be clogged with thousands of miserable sick. There men not only died by hundreds, but, scattering to their homes, carried disease and death to the inhabitants of every colony. But all this was in the web of the future, and the Continental Army, cheered by its recent easy victory, marched confidently on its way to where the enemy next threatened battle before the city of New York.

General Charles Lee had been despatched to New York in February, 1776. Raising a force of twelve hundred men in Connecticut, he marched into the city and assumed the principal authority there, in conjunction with three members of the Continental Congress. New York was threatened throughout the spring, but not actually attacked until July. Washington did not believe that the place could be held; there were so many points to be fortified and defended with his loosely organized and poorly supplied army that it seemed next to impossible to maintain all of them. He proposed to retire to the Highlands of the Hudson and defend the Colonies there; but the Congress decided that New York must be held, and he promised his "utmost exertions, under every disadvantage." When the British entered the river with men of war and threatened to cut off his forces, it was quickly proved to be a place that could not be defended in the face of command of the sea.

General Lee projected works on Long Island, at the Harlem, and at various points along the shores of the island. In February he was succeeded by Lord Stirling. When Boston was evacuated in

March, a large part of the Continental Army was moved to New York, and King's College was taken for a hospital on April 6th. Washington himself arrived on April 16th; going on to Philadelphia to visit the Congress in May, he left Putnam in command in New York, and Greene in charge of the works on Long Island. These generals held their respective commands until shortly before the Battle of Long Island. Washington found about eight thousand men in and about New York, poorly armed and equipped. On leaving Boston, five of the New England regiments had been left behind, and some had been sent to join the Northern Army, but the brigades of Heath, Sullivan, Spencer and one other had marched to New York. These brigades were of about five regiments each and may have numbered twelve to fifteen hundred men to a brigade. At New York the army was joined for the first time by regiments from the middle states.

The camps at New York were marked by much serious sickness, especially by typhus, which had scarcely been seen at Boston. There was also much dysentery, though this disease was seldom fatal. Dr. James Tilton said of the camps at this time:

The ignorance and irregularities of our men in the new scene of life subjected them to numberless diseases. The sick flow in a regular current to the hospitals; these are overcrowded so as to produce infection, and mortality ensues too affecting to be described.

Our Revolutionary Army exemplified this misfortune in a shocking manner. The Flying Camp of 1776 melted like snow in a field; dropped like rotten sheep on their straggling route home, where they communicated the camp infection to their friends and neighbors, of whom many died.

Rush said afterward:

It is very remarkable that while the American Army at Cambridge, in the year 1775, consisted only of New England men (whose habits and manners were the same), there was scarcely any sickness among them. It was not until the troops of the eastern, middle, and southern states met at New York and Ticonderoga, in 1776, that the typhus became universal, and spread with such mortality in the army of the United States.

Dr. Schoepff, chief medical officer of the Hessian force, which reached Staten Island in June, said that scarcely a man escaped sickness during that first summer. The principal disease was dysentery.

The officers of the army were not ignorant or entirely careless of sanitation, but the state of general knowledge and prevailing discipline made enforcement of orders difficult or impossible. On

*This article, which will appear in four instalments, is a chapter from a book to be published shortly.

July 28th the following order was issued from Headquarters of the camp on Long Island:

The General is pained to observe inattention to the digging and filling of vaults for the Regts &, the General directs camp colourmen (colored men?) of the several regiments to dig vaults and fill up the old ones every three days; and that fresh dirt be thrown in every day to the vaults; and that all filth in and about the camp be buried daily.

This order, if enforced, would have resulted in camps as sanitary as those of the Spanish-American War, one hundred and twenty-two years later. Unfortunately it was poorly enforced, as it was in 1898.

In February, General Lee, in a letter to Congress, suggested that a hospital be established in New York without loss of time. The work of building a hospital in New York (the second in America) had been commenced in 1771 and finished in 1774, to be burned down and rebuilt in 1775. But the necessity for barracks preceding that for a hospital, the unfinished hospital building, at the recommendation of the Committee of Safety, was occupied by the troops as quarters. It was afterward used by the British troops, but chiefly as barracks. Private homes were taken and (with King's College) formed the principal reliance for hospitals. They were safer, on account of the consequent separation of the sick, during the prevalence of dysentery and typhus. On April 3rd, while still in Boston, Medical Director Morgan received the following letter from the General:

As the Grand Continental Army . . . will, as soon as it is practicable, be assembled at New York, you are, with all convenient speed, to remove the general hospital to that city. As the sick in the different houses cannot be moved, but must be attended to until they are able to march, you will leave such surgeons, surgeons' mates, apothecaries, and attendants under the direction of (Surgeon to be selected by Dr. Morgan) as are necessary for the care of the sick now in the general hospital. The medicine, stores, bedding, etc., etc., not immediately wanted in the general hospital, should be loaded in carts, that will be provided next Saturday by the Asst. Q. M. General, and sent under the care of a proper officer, or officers of the hospital, to Norwich, Connecticut. Upon their arrival there they will find his Excellency's orders, and how and in what manner to proceed from thence, whether by land or water.

The medicines ordered upon his Excellency's application, by the honorable the General Court of this Province, to be taken out of the town of Boston, should be sent with the first of the hospital stores that go to Norwich, a careful person having order to take charge of the same.

The fixing and completing of the regimental chests, according to your plan, had better be deferred until your arrival at New York, when they may be set about under your inspection.

Before you leave Cambridge it will be necessary to see a proper regimental medicine chest provided and delivered to each of the surgeons of the four regiments left in garrison there under the immediate command of Major General Ward; also a chest for Colonel Glover's regiment, on command at Beverly.

Reposing entire confidence in your care, diligence and zeal for the service, I remain satisfied of your best exertions for the public benefit.

Given at Cambridge Headquarters, 3rd day of April, 1776.

GEORGE WASHINGTON.

To Dr. John Morgan.

This letter is quoted to show the interest taken by the General even in the details of the medical department of the army.

Dr. Morgan, in his *Vindication*, gives some information as to the sick left behind in the Boston hospitals, and also of the supplies that he had collected. They seem pitifully meagre now, but he evidently was proud of them. Many of these supplies had been abandoned by the British, on leaving Boston.

When the troops marched from Cambridge for New York, all the sick were left behind in the General Hospital, amounting to upwards of 300 men. In less than six weeks, during which time but few died, I was able to discharge the hospital of every man, to settle and pay every account, insomuch as never to have had any further demands from that quarter.

During this time, with little or no expense to the public, but for package and transportation, I collected medicines, furniture, and hospital stores, worth many thousand pounds, and sent them on to New York. The like quantity I apprehended could not be procured in any (other) part of America. Besides these, I was able by means of the subaltern officers in the hospital, some of whom I employed continually at this work, likewise to collect near to the amount of two thousand rugs and blankets, near as many bedsacks and pillows, which were taken up from docks, and were gathered from hospitals and barracks, etc., etc. These being washed and aired, served the last campaign, when none other could be got, and many of them are yet in good preservation (1777). In New York I collected some hundred sheets, fracture boxes, and other useful articles.

It may be thought that I place a higher value on these acquisitions than they merit; be that as it may, I am persuaded that the like could not be obtained for much less than thirty thousand dollars: which is equal to the whole amount of what I have drawn or expended, for the general hospital in the space of twelve months, including the pay of all the officers, and all the expenses of every kind; and for the faithful expenditure of the same I am ready to produce my accounts, receipts, and vouchers, whenever called upon for a settlement. Yet the general hospital has had the constant charge of a number from two to three hundred to a thousand sick and upwards to provide for.

Economy seems to have been one of Morgan's virtues, as it was Washington's. He did well to retain his vouchers, for long after the war ended he was wrestling with Congress over these very expenses. He went on to say:

I am persuaded that of the sick who have been drawn (rations) for in the general hospital, if none of them have been drawn for at the same time with the well men in their regiments, the stoppage of their rations will go a long way toward paying the whole of the expenses the hospital has been to on their accounts for provisions and stores of whatever kind.

Washington found time, in the month of June, probably, to inquire into the expenses of the general hospital. He learned from some unnamed persons what the expenses of a similar establishment should be in the British Army. Morgan says:

In a conference with the General, he (Washington) stated that the expenses of the general hospital should not exceed ten thousand pounds per annum, as some experienced persons had intimated.

Morgan feared it could not be done, but resolved to employ strict economy to keep it within those bounds. He mentions "the advanced price of every article of living and hospital stores," which it seems accompanied that war as well as later, and earlier, ones.

Wishing to know the basis of this estimate of the General's, he wrote to the person who made it, probably Dr. John Jones. He was informed that the estimate of ten thousand pounds was made for a force of ten thousand men, for six months. Mor-

gan estimated that the expense for the Army, on that basis, should be forty thousand pounds for one year—for twenty thousand men, the number then kept on foot. Morgan's administration was extremely economical, as will be better understood when the hundreds of thousands expended by his successors are considered.

At the same time he inquired of this person, who doubtless had been in the British service, to clear up all doubts as to the manner in which the regimental surgeons were supplied with instruments and medicines in that service. He seems to have been informed that such supplies were not drawn from the general hospital. He goes on to say:

The Congress, or your Excellency should give orders for a different mode to be pursued; I considered myself to be bound in duty to keep the British establishment constantly in my eye, as a directory, making allowances for the nature and differences of the service.

At another conference with Washington over difficulties, he, Washington, had said: "What is the practice in the British Army? Why should we think of improving upon their system, founded upon long experience?" It is clear that both the General and the Medical Directors were following the customs and regulations of the British Army, in so far as they could be applied to the Continental Army.

On June 3rd Congress called for thirteen thousand eight hundred militia from the New England Colonies, and ten thousand from Pennsylvania, Delaware and Maryland. These latter were to furnish what was designated as The Flying Camp, for the protection of the Jerseys, threatened with invasion by the British forces. General Hugh Mercer was given the command of this doubtful force, and Dr. William Shippen was made its Medical Director on July 15th. Shippen had been Morgan's colleague in founding the Medical College at Philadelphia, and was later to supplant, if not undermine, him. Mercer was a Scotch physician, a graduate of Aberdeen, who had followed Prince Charlie to Derby and escaped from the slaughter of Culloden. He had served in many Indian campaigns, where he was often wounded. He commanded a company in Braddock's dismal expedition, was severely wounded and left on that field of death, but escaped and made his way back through three hundred miles of wilderness. In 1756 he was both commanding officer and surgeon at McDowell's Fort in Pennsylvania, and was there twice wounded. In 1758 he was an officer under Forbes, fighting with the redcoats now. He entered the war as Colonel of the Third Virginia Line early in 1776. He was made a brigadier on June 5th and given command of the Flying Camp. He was to die by British bayonets, fighting to the last, before the year was out. Of the many heroes of the Revolution none merited that title more than did Dr. Hugh Mercer.

By July, Morgan had established his hospitals in New York, provided them with stores, and was as he supposed fairly well prepared for the coming storm. But as to the regimental surgeons he was in dismay. They had next to nothing, and, most of all, seemed careless or ignorant of their own helpless state. He says:

I am well off in the general hospital, except in a few particulars. I have provided ten thousand bandages, have

some hundred old sheets, and a stock of medicine (though unassorted). I have of capital instruments nearly enough for hospital use. But in the meantime what is to become of the regimental surgeon? Should I divide my stores among them, they would be dissipated and ourselves left destitute. To observe a medium I have orders to be issued from the general hospital stores, sixty bandages, two sheets, four tourniquets, a quantity of lint and tow, and a chest of medicines. . . . But of instruments I have none to spare, and I begin to want some capital medicines. Moreover, symptoms of a putrid fever begin to appear. [Typhus.]

At this time there were about forty regiments with the Army. The hospitals in New York then were: King's College, City Hospital, City Barracks, and whole streets of houses appropriated by the convention of New York. Country seats at a distance of some miles were also taken. King's College was the principal hospital, the others were subsidiary. General Greene complained of the neglect of the sick on Long Island. Dr. John Warren (1), of Boston, was made surgeon of that part of the General Hospital, established on Long Island for the troops there. Dr. Isaac Foster was his assistant. Morgan's letter of instructions (2) to Warren is full and comprehensive.

The hospitals about New York were an improvement on those hitherto established, yet left much to be desired. Especially were the regimental surgeons lacking; not only in tents and bedding, but also in instruments and dressings, of which they had next to none. Morgan inquired into these shortcomings and took what he considered the proper steps for remedying them. While most of his proposed measures were excellent, in one principal one he appears to have failed to hit upon a proper remedy. The regimental surgeons were always short of supplies and were continually applying for them to the general hospital. He always maintained that he had none to spare, which was true. But, instead of proposing a general supply officer, under his own jurisdiction, he proposed a system of continental druggists, located some place and under no control. This was the point on which he failed. He himself admitted afterward that this was the rock on which he foundered, but never admitted that he was in error. His letters and papers at this period, though not always clearly composed, give a complete picture of the difficulties of the general hospital at that time.

In a letter to Congress, in July, 1776, he stated his own case. Morgan may be allowed to tell his own story of his efforts to supply the regimental surgeons and put them on a proper working basis. He says:

A powerful fleet and army from Great Britain intended for the reduction of New York, being likewise already arrived on the coast; and having prepared everything in my department that was in my power, I then considered the unsettled state of the regimental surgeons. In order to bring them by degrees into greater regularity, and to make them more useful in case of action (as many of them had newly entered the service and most of them from want of experience were yet novices in the duties of a military surgeon), I thought it advisable to give them some instruction which might open their minds to a sense of what their duty required of them, as regimental surgeons, in time of action, which it could not be supposed was very distinct. I therefore drew up the following directions and communicated them to the General. He approved of them in the orders of the day; and commanded

the several surgeons of the regiments to wait upon me for copies, and to regulate themselves according to the proposed plan. Each surgeon was allowed a copy, and commonly, at the same time, I gave him an order on the apothecary of the general hospital for a medicine chest, for every battalion: which he also obtained if he was not already provided: together with a number of tourniquets, and a quantity of lint, tow, and old linen for surgical dressings.

The order and instructions are worth repeating here in full:

Order and Instructions Given to the Regimental Surgeons in Case of Action.

NEW YORK, July 3, 1776.

It is proposed by the director general, and ordered by his Excellency, the Commander in Chief, that the regimental surgeons and mates may be the better prepared for the discharge of their duty, in case of action, to hold themselves in immediate and constant readiness for service; and, in the first place, to make a return to the director general of the hospital, of those names and stations, and of the instruments and bandages, etc., they have on hand, agreeable to the following form:

A regimental return of surgeon's instruments and bandages, etc., now in readiness for medical service; belonging to Colonel Regiment, in Brigadier General Brigade, encamped at July 3, 1776.

Name.	Instruments on hand for use.	Number and kind of bandages, ligatures, etc.	Old linen and other implements.
Surgeon	Amputating instruments	Simple rollers	Quantity of linen or weight of rags
	Trepanning instruments	Foliated bandages	Weight or quantity of lint
Mate	Incision knives	Splints	Tow or sponges
	Pocket instruments	Tourniquets	
	Bullet forceps	Ligatures	
	Crooked needles	Tape	
	Straight needles,	Thread	
	Pins		Signature

As the general hospital will not admit of the hospital surgeons and mates being divided or detached, and may require occasional assistance from the regimental surgeon, in case of many wounded being sent to it, the following regulations are to be observed for the present, and till any change of circumstances may require an alteration.

Part of the general hospital is now fixed at Long Island, for the reception of sick and wounded persons, whose cases may require it; which John Warren, Esq., Surgeon in the General Hospital, is appointed to superintend and direct, with the assistance of three hospital surgeons and mates, and such other regimental surgeons and mates, belonging to that part of the army stationed at Long Island, as may be required. In case of evident necessity, arising from an attempt being made on Fort Defiance (afterwards called Fort Washington), two of the hospital mates with Dr. McHenry, now at Montrossor Island, and whom he is to superintend and direct, are to repair to that post, with a proper assortment of medicines and bandages.

The remainder of the surgeons and mates of the general hospital are to continue at King's College and New York Hospital, for the reception of such wounded as are sent to them, from whatever part.

It being the duty of the regimental surgeon and mates, in case of action in the field, to attend the corps to which they belong, in order to dress the wounded in battle; they are to take post in rear of the troops engaged in action, at the distance of three, four or five hundred yards, behind some convenient hill, if at hand, there to dress the wounded who require to be dressed, on or near the field of battle.

If the regiment or corps to which they belong are engaged within a fort, or lines thrown up for defense, that fort or place of defense is then the proper station for the regimental surgeons. But as a regiment may be divided, and distributed into different posts, so as to render it impracticable for the regimental surgeon and mate belonging to that regiment to be near some part of their corps, it is necessary that an account of the number of surgeons and mates in any brigade or any division of the army that occupies one or more detached posts be taken, and delivered to the commanding officer of said posts or divisions. It is

to be considered as the duty of each regimental surgeon and mate respectively, wherever stationed, to regard himself as having a joint charge of the whole brigade, with the rest of the surgeons of that brigade, rather than as if his care was to be confined only to those officers and soldiers who are of the regiment to which he belongs. It must unavoidably happen, at times, that both officers and soldiers may be wounded in action, and their particular surgeons be elsewhere employed, so as not to be able to attend them.

The amputation of a limb, or performance of any capital operation, cannot well take place in the heat of a brisk action. It is seldom possible or requisite. What the surgeon has chiefly to attend to, in cases of persons being much wounded in the field of battle, is to stop any flow of blood, either by tourniquet, ligature, lint and compress, or a suitable bandage, as the case may require; to remove any extraneous body from the wound; to reduce fractured bones; to apply proper dressings to wounds; take care on the one hand not to bind up the parts too tightly, so as to injure the blood circulation, increase inflammation, and excite a fever; or, so loosely as to endanger the wounds bleeding afresh, or to allow broken bones, after they are properly set, to be again displaced. The wounded being thus dressed by the regimental surgeons, are next to be removed to the nearest hospital belonging to the brigade, or to the general hospital, as may be most convenient.

As the general hospital may at times be fully crowded with sick persons, or in the time of action, so many wounded may be sent there, as to require a greater number of hands than that part of the general hospital, where many of the wounded are sent, is furnished with, it may be absolutely necessary for the superintending surgeon, besides the proportion allowed him from the general hospital, to call for the assistance of a number of surgeons and mates from the brigade, division, or post of the army where he is, either before an engagement, or, when the number of wounded persons sent to him becomes very great, making such assistance needful. For this purpose he is to apply to the commander of the brigade, or any part of the army, who is hereby ordered to send him as many regimental surgeons and mates, for that purpose, as are required and can be spared from their posts.

To prevent confusion, and that the regimental surgeons may know the better what part of duty is expected from them, some one, at least, of the surgeons, especially those fixed at outposts, are directed, as soon as possible, to call upon and arrange matters, in time, with the hospital surgeons nearest at hand, in behalf of the brigade, or corps acting together, that no disorder may arise, in time of action, for want of so necessary a precaution. The regimental surgeons ought to call on the officers of the corps to which they belong, to settle with them, what persons are to be employed in carrying off the wounded, and for a supply of wheelbarrows, or more convenient biers, for conveying them from the field of battle to the place appointed for reception of the wounded, or general hospital. Each regimental surgeon and mate ought to have a portable box, with suitable divisions for containing his lint, bandages, instruments, and other implements of surgery, which ought to be well provided with every necessary.

In applying a common tourniquet to stop the flow of blood from any principal artery in a limb, till it can be otherwise properly secured, care must be taken not to twist it too tightly above the limb; and to prevent the tourniquet from slipping, so as to endanger a fresh loss of blood, it must be fortified with a ligature of thread or tape.

JOHN MORGAN,
Director General.

This circular of instruction, though in places most clumsily worded, contains much useful information and directions. The direction as to placing the dressing station behind a convenient hill is naïve. The reminder that a surgeon should not confine his attention to his own organization, but should attend any man in need of help, his own proper surgeon being absent, was very necessary. The fear of too tight a tourniquet causes him to refer to it twice. The mention of wheelbarrows and biers for

the wounded makes it apparent that no real standard litters were then in use. The Dr. McHenry mentioned was he for whom Ft. McHenry at Baltimore was afterward named.

He attempts to overcome the difficulty of requiring regimental surgeons to assist at the general hospital, which they then, as now, did not desire to do, but the scheme is involved and lacking in force. Throughout the circular there is much mingling of what will be done and what ought to be done. Yet, on the whole, this circular shows that Dr. Morgan had a clear conception of the situation and what should be done; that he was attempting, under the greatest difficulties and inertia, to get these things done. He states, later, what success or lack of success he had in his endeavors. His statements list the complete surgical armamentarium of the regimental surgeons of the Continental Army at that time. It was meagre beyond imagination. There were then about forty small regiments in the Army at New York. They averaged little more than 300 men each.

In consequence of the foregoing plan and orders, some reports were made, although they came in but slowly. Near a fortnight passed over before I received them from more than fifteen regimental surgeons. It is to be ascribed, if not to that backwardness which the regimental surgeons ever showed to complying with general orders; perhaps to a conscious shame of being entirely destitute of any necessary articles, but what they had previously indulged to draw from the general hospital: Some of them, whom I afterwards met, and inquired into the cause of their neglect, confessed this to be the truth.

As my intention in desiring these reports to be made to me, was to lay them before the General and Congress, with remarks on their insufficiency, that the medical committee might be incited to use more diligence, than heretofore, to fall on some measures for supplying the regimental surgeons with every necessary to qualify them for greater usefulness in their station. I drew up, from the separate reports delivered to me, one general return of the state of the above mentioned fifteen regiments. All the instruments were reputed to be private property, and amounted to:

- Six sets of amputating instruments.
- Two sets of trepanning instruments.
- Fifteen cases of pocket instruments.
- Twenty-five crooked and six straight needles.

Among the whole fifteen surgeons there were only four scalpels or incision knives, for dilating wounds, or any other purpose; three pairs of forceps for extracting bullets; half a paper and seventy pins and but few bandages, ligatures, or tourniquets; and as little old linen, lint or tow, but what they had procured from the general hospital; and only two ounces of sponges in all. Amazing deficiency for fifteen surgeons and as many mates!

Upon inquiry how they could think of marching with their regiments, without at least providing old linen for dressings; or of joining the army without the necessary instruments, as, if ever they reflected at all they must be sensible of the impropriety of so doing, and of its being much easier for each man to procure those articles, within the sphere of his acquaintance, connexions, or neighborhood, than to obtain them in an army, in general destitute of necessary supplies, of what was not to be procured in America, but with great difficulty: Their constant answer was, whenever they applied to their superior officers for those things, they were always told, they would be furnished with everything they wanted, as soon as they should have joined the army. Upon being informed that I had only a sufficiency of those things for the general hospital, and that I would by no means unfurnish it to supply them, they appeared quite confounded, and expressed great uneasiness, at having no proper establishment; and said, they knew not how, or where to obtain the necessary articles, to be anyways useful in the army, if I did not assist them.

As I was not ignorant of the many inconveniences under which they had hitherto labored, from a want of attention in the Congress to relieve or place them on a better footing, and as I felt for their distress, I assured them of my readiness to assist them, all in my power, confidently with my proper duty, and the orders I had, or should receive from Congress. I asked them to meet in a body; to converse on the matter with each other; and then to choose one or more deputies from each brigade, to state their helpless situation, and pray for relief; in which I was willing to second their application, with all the influence of which I was master.

As they complained much of not being allowed proper regimental hospitals, and as I had, in opposition to what appeared to me to be the sentiments of both the Congress and the General, ever uniformly given it as my opinion, that regimental surgeons and regimental hospitals, under proper regulations, and due subordination to the general hospital, might be very useful. I took that matter under my consideration. I likewise drew up a memorial, and proposals, to be shown to the General, for his approbation and concurrence, to be laid before Congress. At the same time I penned for the use of the regimental surgeons, a form and directions for keeping a proper register of the sick, and for making every kind of necessary returns of sick, provisions, etc., etc., also tables of the various kinds of diet used in the general hospital, as are examples for themselves to copy after; under the heads of: full diet, half diet, low diet, milk diet, and fever diet; with the method of calculating the difference betwixt these, and the amount of the well rations; to enable them to draw the value of the difference, whether in cash or refreshments, but for the use of the sick only: And I showed them a list of what instruments, bandages, ligatures, lint, tow, old linen, and other articles I esteemed necessary for a Regiment; which I shall subjoin to the substance of the memorial and petition to Congress, and the proposals I had sketched out for their consideration (3).

At an appointed meeting with the regimental surgeons, before producing the papers referred to, the director addressed them in a prepared speech, which he had the forethought to preserve (3).

(To be continued)

HISTORICAL NOTES ON THE PRACTICE OF MEDICINE IN NEW YORK CITY.

BY G. L. ROHDENBURG, M. D.,
New York.

It has recently been my good fortune to be permitted to search the Whitehead Library of the Lincoln Hospital and Home of New York for items of historical interest in medicine. This library was founded by Dr. Whitehead, and consists not only of his own library but also the libraries of Dr. Livingstone, one of the founders of the long defunct Queen's Medical School, and of Dr. Sabine, who was for many years a member of the faculty of the College of Physicians and Surgeons, New York. Many of the volumes, particularly the older ones, are importations from England, and are either the works of English authorities now more or less forgotten, or translations from some other European language. A fair number are early American works dating from 1778 to 1804. In a survey of these volumes I have gleaned a number of somewhat disconnected items which are perhaps of more than passing interest at the present time.

Among the things of interest which have been found are a series of facts having to do with the early history of medicine in the City of New York. During the supremacy of the Dutch West Indian Company in New Amsterdam, the names of Johan-

nes Megapolensis and of his son Samuel appear as the prominent physicians of the period. A little later the names of Johannes La Montague, also a prominent physician, and of Abraham Staes and Hans Kierstede, both of much repute as surgeons, are found in the records. The last named had a daughter, Tryn Jansen, who was a famous midwife. At a still later period, Gerardus Beekman is mentioned.

The first postmortem occurring in the city was performed on the body of Governor Slaughter, who died under suspicious circumstances in 1691; and it is recorded that the physicians performing it were paid eight pounds six shillings for their investigation. The first anatomical dissection was performed by John Bard and Peter Middleton in 1750; and the first medical school was founded in 1767 by the group consisting of Samuel Bard, Middleton, Clossy, Smith, Tennant, and Jones. Middleton was selected as the first professor of pathology and physiology in

physicians displayed great discretion by remaining within doors.

In 1807 the College of Physicians and Surgeons was founded; and in 1814 this institution united with the Medical School of Columbia College. The equipment of the institution was exceptionally poor, for it is recorded that in 1814 the three students used umbrellas in the lecture halls on rainy days. The course in anatomy consisted of the dissection of one body a year.

The deficiencies in education were to some extent corrected by the formation of medical societies for the exchange of views on medical matters and for the development of sociability; thus the Physico Medical Society was founded in August, 1815, and in 1823 the New York Kappa Lambda Society of Hippocrates was started.

The New York Pathological Society was founded in June, 1844, the first meeting taking place in the

PENNSYLVANIA HOSPITAL, 1820

the medical school of King's College, which in 1784, after the Revolution, became Columbia College. The first medical degrees were granted in 1769, when Samuel Kissam and Robert Tucker were made Bachelors of Medicine.

The medical school having been founded, the troubles of the faculty began in their inability to obtain anatomical material, for which reason the students and faculty acted as their own resurrectionists. Even Valentine Mott confessed to his share in such proceedings. This resurrectionist habit led to the famous Doctors' Riot, which occurred on April 13, 1788, lasted two days, and cost ten lives, troops being called out to repress the disturbance. Numerous prominent individuals were injured, among them Baron Steuben of Revolutionary fame. The inciting cause of the disturbance was the incautious exposure of a pair of freshly varnished and dissected legs hung out of the college window to dry. Dr. Cocks states that for the period of the disturbance the

office of Dr. Lewis Sayre at the corner of Broadway and Spring Street, but a short distance from the old quarters of the Queen's Medical School at Duane and Hudson Streets. The College of Physicians and Surgeons, which subsequently became the meeting place of the society, was at that time located on Crosby Street. Dr. Sayre had the doubtful honor of disposing of specimens after the meetings by throwing them into the Hudson River. At one time he was almost caught by the police, and at the next meeting his confrères urged him to be more circumspect—this not in the tenth century, but in 1847.

Even in those days civic pride, which is now typified by a statue atop of the Municipal Building, was a fully developed and vigorous movement. Some of the inaugural addresses before the Academy of Medicine, which was founded in 1847, are almost tauntingly boastful of the achievements of the medical men of New York City.

Dr. McGrath, the first hydrotherapeutist in th

city, has been immortalized by Smollett. Vaccination against smallpox was first introduced into the city by Dr. Seeman, and inmates of city institutions were first vaccinated by Dr. Beekman Van Buren. The New York Hospital, first located on Bedloe's

RUDOLF VIRCHOW

Island, was founded in 1771 and incorporated in 1790. James Stringham was the first professor of legal medicine, and Governor Eddy of New York authorized the establishment of the first insane hospital in the United States.

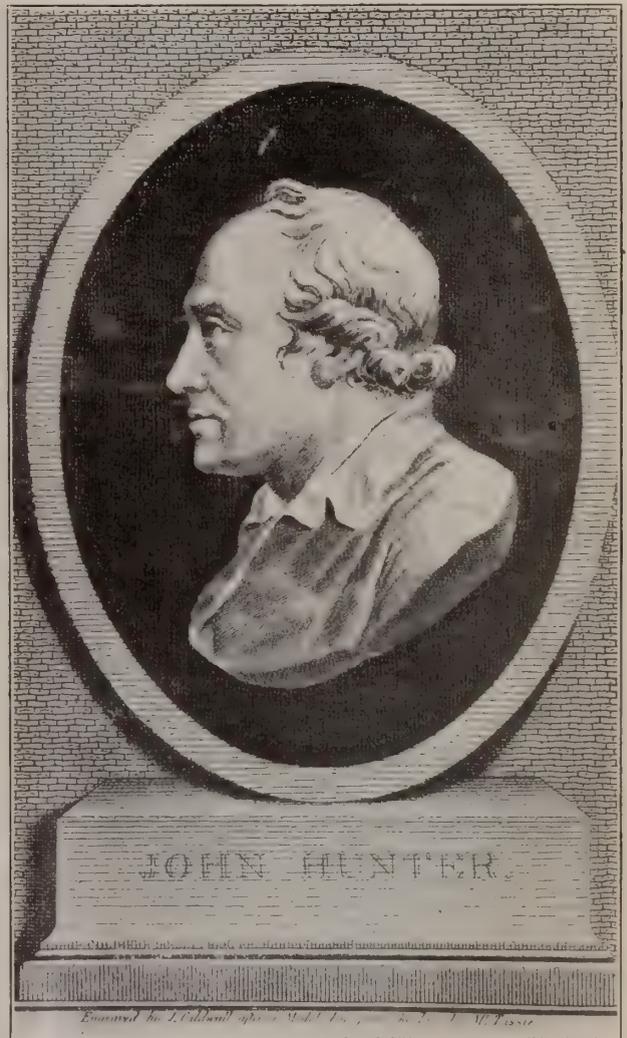

Among other causes for civic pride, as having been first performed by residents of the city, were the following operations: Ligature of the arteria innominata, ligature of the left subclavian artery within the scaleni, division of the esophagus for the relief of impermeable stricture, extirpation of the upper and lower jaw, excision of the elbow joint, and scarification of the interior of the larynx. To us of the present day these may not seem to be wonderful; but in those days aseptic surgery was not dreamed of, and antiseptic surgery had not yet been born; even anesthesia was but in its very infancy. In fact, Dr. Valentine Mott was so impressed by the fact that he had seen, in 1818, a case of compound fracture of the femur in which recovery had actually occurred that he thought it worth while to report it in detail.

There are before the profession today problems which had their counterpart in the older days under different names, and since history is but the experience of bygone generations, the terse and forcible

Anglo-Saxon in which they described their troubles may also interest us. In 1849, the three most prominent patent medicine dealers in the city were an insolvent drygoods store keeper, a clerk in a lamp store, and a bookbinder. In denouncing these parasites, Dr. Francis remarked:

"In a few instances the powers of quack medicine have been so highly esteemed, that large sums of money have been given to the owners to reveal their secret composition; but as soon as the mystery has been unraveled the charm has disappeared, and the remedy which was once regarded as so important has been consigned to oblivion, the common grave of quacks. The remedies which are now so much esteemed on account of their working powers, will undergo the same fate, and other Swains, and Morrisons, and Grandfathers, will appear in other days to reap an income from the credulity of the ages in which they shall live, and like those who have gone before them will in their turn be forgotten."

In the early years of the last century the question

of cults and isms was also a crying problem. The chief of the new fads at that time was homeopathy, and from a scathing arraignment of the entire fad the following quaint doggerel is copied. It was quoted as being a typical application of the principle

of infinitesimal dosage carried to the point of *reductio ad absurdum*.

Take a little rum, the less you take the better.
Pour it in the Lakes of Wenner and of Wetter.
Dip a spoonful out, mind you don't get groggy;
Pour it in the Lake of Winnepissigogge.
Stir the mixture well, lest it prove inferior;
Then put half a drop into Lake Superior.
Every other day take a drop in water.
You'll be better soon, or at least you ought to.

In a discussion of the necessity for higher education preliminary to the study of medicine, Alexander Stevens put his finger upon an extremely sore spot, one in existence even today. "The defect of American character, as regards scientific requirements, is overweening selfconfidence, or an undervaluing the necessity of technical knowledge for the successful pursuit of the learned professions, and consequently a lamentable deficiency or superficiality in their acquirement."

Dr. Francis in the same year commented rather acidulously upon the action of the State Legislature in letting down the requirements for the right to practise medicine: "Nothing but the poverty of language debars me from a suitable expression of opinion of that calamitous proceeding of our State Legislature which has broken down the door of the temple for all who please to enter and administer."

The ethics of newspaper publicity also aroused a considerable storm in the early meetings of the New York Academy of Medicine, Isaac Wood in a vigorous discussion drawing the attention of the members to the fact that, "so far as they have been made,

opposition to established principles, for it is rare that time does not prove them to have been without foundation; especially do not be misled by reports of wonderful cures or the efficacy of new operations." Well might the opening phrase of the sentence be emblazoned upon the editorial page of every newspaper in America.

The more jovial aspects of the profession are exemplified by the accompanying cartoon drawn by

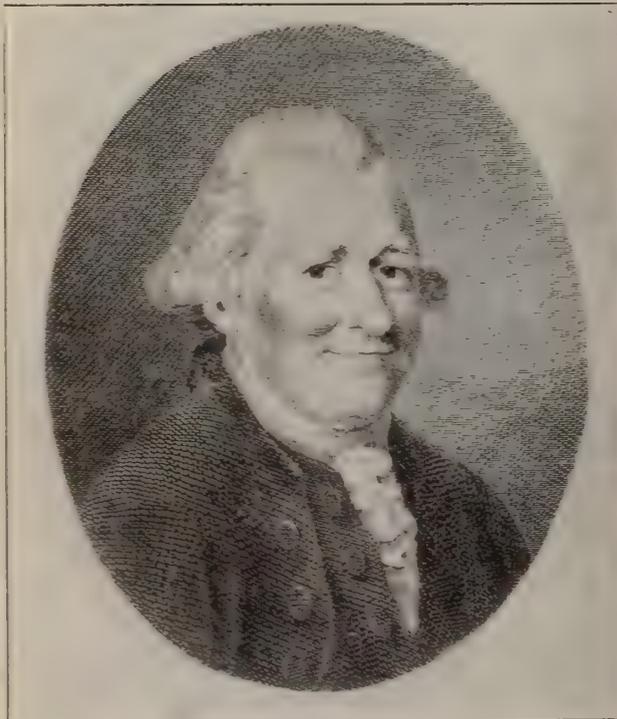

Cartoon depicting a quiz in the office of Dr. Willard Parker.

Dr. Sabine and depicting a quiz in the office of Dr. Willard Parker. Prohibition was not then in vogue, though Dr. Valentine Mott publicly protested against the rum ration of medical students as too large, a half pint *per diem* being allowed. Whether the large pot in the foreground is a receptacle for tobacco cuds or, as might be deduced from the title of the cartoon, a precaution against gastric upheaval, the artist leaves to our imagination. The other illustrations of the present article are presented because of the excellent work of the engraver. One is of John Hunter, best known to the younger generation because of his association with the recognition of chancre. Another is of John Brown. A third is a hitherto unpublished photograph of Virchow, the founder of cellular pathology; while the fourth will be readily recognized by the inhabitants of the City of Brotherly Love.

From a scientific viewpoint the old volumes record the alert mentalities and acute powers of observation of bygone generations. To those who passed through the influenza epidemic of 1918 it may be of interest to know that almost one hundred years ago Graves described a similar epidemic in Ireland. His description of the gross pathology fits the condition so exactly that with the addition of the label: "From the laboratory of the XYZ Hospital," it might have been written but yesterday. The bronchiolitis, the absence of complicating empyemas, the intense congestion, the persistent cough, the following incidence of tubercle, the alopecia, are all wonderfully clearly described, as Graves says, for the benefit of posterity, so that eventually the cause of the disease may be discovered. He states that such epidemics have been known for over 200 years, and points out the differences between influenza and bubonic plague.

Another item of interest is the preface to the

JOHN BROWN

the reports of our proceedings in the public prints have not advantaged us either collectively or individually." Alexander Stevens at the same time warned the newspaper reporters that they should "be cautious in giving credence to alleged facts which are in

first English edition of Koch's *The Infectious Traumatic Fevers*. Cheyne, who wrote the preface to the translation, betrays his origin by his conservatism, for one sentence reads as follows: "The reader of the following work cannot fail to admit the beauty and importance of the observations which it records provided he can be satisfied of their authenticity." Thus was the demonstration of the cause and mechanism of sepsis greeted upon its translation into the English language.

The opinion of the older American surgeons upon the surgery of cancer is well represented by Alexander Stevens, who in a report of cases of fungus hæmatodes of the eye (melanosarcoma) appearing in the *Medical and Surgical Register* of the New York Hospital for 1818, mournfully concludes:

"From these gloomy details not one ray of consolation can be derived. The occurrence of disease in parts distant from the primary affection (metastasis) in the last two cases is too remarkable to pass without notice. It naturally tends to the conclusion that the disease is not local, and offers a strong inducement to the surgeon to limit his views to the smoothing of the avenues to the grave from which he can neither free nor respite his unhappy patient."

905 WEST END AVENUE.

DENTAL INFECTION.

By SINCLAIR TOUSEY, A. M., M. D.,
New York.

Dental infection is no new thing. Benjamin Rush over a hundred years ago cured cases of rheumatism by ordering the extraction of infected teeth. It is now known that infection may exist for years without local symptoms, pain, or swelling. Probably in many cases the infected teeth could have been found by the dentist before the days of the x ray, but now this examination shows the condition in many cases as clearly as it shows a fracture of the bones of the leg.

A dead and putrified nerve or tooth pulp is full of germs from which poison is absorbed into the system. This may go on for years, since the pulp chamber in the tooth cannot collapse like the walls of any ordinary boil or abscess and the lesion undergo spontaneous cure. The amount of absorption from an abscess at the apex of the root of a tooth is not indicated by the small size of the abscess cavity but by the rapidity with which the poison is generated and the freedom with which it is communicated to the blood. The free bleeding which ordinarily ensues when a tooth is extracted illustrates the anatomical fact that the tooth is not like an inanimate glass plug in the tooth socket but is a vital organ with blood vessels which must be torn in order to extract it. Through this free blood supply the poison from a blind abscess is poured into the system at a speed of which we can obtain some idea from the other class of dental infection, pyorrhea. In the latter case we may be able to press a large drop of pus from the pocket surrounding the root of a tooth every five minutes.

Two kinds of poison are absorbed; the germs themselves and toxins or their poisonous products.

The germs enter the blood but there they are ordinarily destroyed by certain white blood cells called phagocytes, and even in many cases of serious or fatal disease unmistakably due to dental infection, the germs do not grow and multiply in the blood and may not be discoverable in it. This is true in regard to certain other germ diseases. For instance, in a case of tuberculosis we look in the sputum, not in the blood, for the tubercle bacilli. When the normal resistance of the blood to invasion by the germs from a focus of infection has been lost or greatly reduced, then the germs may multiply in the blood and usually with a fatal result. A pint of blood drawn from the body, cooled and therefore devitalized, may be experimentally infected with the pus from an extracted abscessed tooth and if kept at a temperature of about 100° F. will in a few days become a mass of living and multiplying germs sufficient if divided up in hypodermic doses to kill a company of one hundred soldiers.

In many cases where the germs never succeed in growing and multiplying in the blood, some of them are carried by the blood and lymph to places where they form a secondary focus of infection. A clot or vegetation may form in the heart valves, full of the living and multiplying germs. This occurrence is commonly the beginning of a lingering and painful death. Fragments of the infected vegetations break away and are carried by the blood, and blocking up small arteries cause paralysis, pneumonia, and a host of other complications affecting every organ and function of the body. This painful and hopeless illness often lasts many months and all that time there is a possibility of sudden death from blocking of a large artery in the brain.

Happily a dental abscess almost always produces symptoms due to absorption of poisons before any direct germ extension takes place. These symptoms are as manifold as the different organs to which the blood carries the poison. Two persons seldom are affected in exactly the same way. Some of the subjects have high blood pressure with a tendency to result in arteriosclerosis and finally apoplexy and death. Others have one or other of the different lesions and symptoms called rheumatism. Others have neuritis, neuralgia, and various eye troubles which formerly seemed to be due to rheumatism, one eye even having been saved by the treatment of a tooth abscess discovered too late to save the other. Indigestion is a common effect. And there is a general agreement with the Mayos that ulcer and cancer of the stomach and cancer of the gallbladder are usually due to dental infection. Skin diseases and insanity are in many cases due to dental infection. A complete list of conditions which may be caused by dental infection would be a very long one.

We often hear it said that this is a temporary fad, like removing the tonsils for rheumatism. And again the physician who recognizes the possibility and even the strong probability that the patient's symptoms indicate the presence of dental infection too often is asked, "You want me to have all my teeth out?" It is true that many cases of rheumatism and other diseases are due to infected tonsils. That was not a temporary fad but is today the

means of restoring health and saving lives. We know that the teeth also are a source of infection and we know that a focus of infection may sometimes be found in the sinuses and that sometimes autointoxication may develop from primary intestinal conditions.

These facts do not make it a fad to examine the

FIG. 1.—Radiograph of jaw of skeleton showing mental foramen.

tonsils or the teeth or the sinuses or the intestines and to cure any focus of infection that is discovered. Particularly in regard to the teeth, the x ray enables one to acquit the healthy teeth and it certainly would be a fad to go ahead and blindly extract all the teeth, good and bad, in a case of rheumatism.

That the different diseases and symptoms referred to are often caused by a focus of infection and that many of them if taken in time are cured by the eradication of the focus of infection is not the theory of one person or of any group of persons. It has been tested and proved by many physicians, surgeons, and dentists in many different countries. The tests as to causation have been similar to those establishing the fact that typhoid fever is caused by typhoid bacilli and cholera by the cholera bacillus.

A great variety of symptoms are known to have dental infection as their frequent, common or even usual cause. These symptoms may not be serious in themselves and if they are due to dental infection that cause may be left undiscovered and untreated for years. Delay in the discovery of the

dental infection may occur because the idea had not occurred to the physician, or the patient may delay the x ray examination because of a fear that one or more teeth may have to be extracted. This delay cannot possibly enable the infected tooth or teeth to become normal. It simply results in their getting worse and, whereas at an early stage the dentist is often able to treat and cure and preserve an infected tooth, an advanced stage may be reached where only extraction is possible. The sooner an infected tooth is discovered and cured the greater is the hope that others may not become infected.

The idea used to be that an old snag of a root ought to be preserved at all hazards to prevent absorption of the alveolar process and falling in of the cheek. This is a dangerous theory and in actual practice many a patient has been poisoned by pus from an infected retained root. And the x ray has often demonstrated extension of pyorrhea from such a root as the cause of destruction of the alveolar process of a neighboring tooth. A perfectly good tooth may be sacrificed by clinging to a dangerous and useless root.

The lower bicuspid apices are close to the mental foramen, an opening in the lower jaw through which a nerve passes to the chin and lower lip. A radiograph (Figs. 1 and 2) of the lower jaw of a skeleton shows this opening in an unmistakable way, but the foramen has no such characteristic appearance in a radiograph of a living person. Indeed it often looks very much like a periapical abscess of the second lower bicuspid and has doubtless been frequently mistaken for one. It is only necessary to be on one's guard against this error and in case of doubt to make a radiograph of the second lower bicuspid on the other side of the face. An identical appearance of the right and left lower second bicuspids would be the strongest indication that the appearance was a normal one due to the mental foramen.

It has long been known to the author that a vital tooth may show periapical infection and he has made a radiographic diagnosis of periapical infection in teeth which were vital, some with and some without pain. A lower molar pulp may die in one root canal and be alive in the other and in the pulp chamber. As a rule if the radiographic appearance is doubtful it is recommended that the vitality of the tooth be tested by heat or cold or by faradism. And if found to be vital the tooth is given the benefit of the doubt. Where, however, the x ray appearance is unmistakable, even though the tooth may respond to heat and cold and faradism and be exquisitely sensitive when drilled into, then the interests of the patient require that the nerve be killed or the tooth extracted. The latter would be called for if the radiograph showed such a bending of the root that disinfection of the root canal and of the periapical abscess cavity would be impossible. With pain and swelling, in fact with the ordinary symptoms of a dying nerve, the dentist has never been at a loss as to the proper treatment. But without the x ray it is not always possible to determine promptly which tooth is affected and I have walked the floor twelve nights while a tooth four spaces from the affected one was being treated.

It was a case of the shoemaker's children going barefoot, and the moment a radiograph was made the error was discovered. And even in the right tooth the x ray will sometimes be required to trace the root canal and the way into the abscess cavity. Guided by the radiograph the dentist presses his drill in the right direction, it enters the abscess and pus wells into the pulp chamber.

It is the cases of a vital pulp without pain or swelling but with unmistakable x ray evidence of periapical abscess that are the most difficult for the dentist to decide about and he may very probably ask to have another corroborative radiograph made before reaching a decision.

An important discovery has just been announced by Hartzell and Henrici to the effect that pathogenic germs are often found in the vital pulps of the teeth affected by pyorrhea or having carious cavities. Their experiments were conducted in such a way as apparently to prevent artificial infection of the pulp, and in twenty-six healthy teeth extracted and opened in the same way the pulps were all found aseptic. This agrees with my own observation of many vital teeth with periapical infection.

From some cause the radiograph of a dead tooth which has been treated and filled may show the root canal only partly filled. This appearance may be due to the use of a transparent filling material or to the filling being actually incomplete. In the latter case a space remains permanently which is exceedingly prone to infection. And when there are symptoms of infection it is often necessary for the dentist to treat the root canal and fill it completely.

Many authorities favor the extraction of every dead tooth, but there are many others who believe that a dead tooth can often be sterilized and be kept in that condition for many years and for all that be a harmless and useful member. A dead tooth is of course always under suspicion and to be kept under occasional x ray observation. At the first indication of its being infected treatment through the root canal should be instituted and if it becomes infected time after time for a period of years, the rule seems to be that what can't be cured must be extracted. Of course many a time the radiograph reveals such an extent of necrotic bone, or the symptoms of systemic poisoning are so severe that one's effort should be not to save the tooth but to save the patient.

The condition in which the tooth is found after extraction is an important subject for consideration. The tooth itself may in some cases appear normal or close scrutiny may show a small area at the foramen where the natural smooth surface is lacking. We know that an infected root canal and an infected periapical space causing systemic infection do not necessarily involve any marked change in the gross appearance of the extracted tooth. The dentist and the patient should not for a moment suppose that the tooth was harmless or even a desirable possession because it looks practically normal after removal. We can tell from the radiograph before extraction whether the root has been denuded or eroded, and if so, to what extent. And changes in the tooth itself are not the decisive

factor in deciding that a focus of infection exists which if not capable of cure by treatment through the root canal requires extraction.

The fang of a rattlesnake or the needle of a hypodermic syringe may be perfectly smooth and still convey an active poison. The putrescent pulp of a tooth may poison the system through the apical foramen without any necessary change in the gross appearance of the root.

We sometimes hear that some dentist has told a patient that a blind dental abscess will sometimes exist for years without causing illness. The inference is intended to be drawn that if you have symptoms or lesions which all dental, medical, and surgical authorities state are often caused by dental infection, it is just as well not to have an x ray examination and when one is made and shows the existence of a blind abscess the inference these people suggest is that it may just as well be left untreated and uncured.

I do not believe that at the present time any dentist would make the statement unqualifiedly or would draw these conclusions from it. But years ago this was the case and the following history shows the natural result of such beliefs.

CASE I.—Dr. S. was referred to me for the treatment of neuritis of the shoulder and forearm by

FIG. 2.—Radiograph of lower jaw of skeleton showing mental foramen.

high frequency currents applied from ultraviolet ray vacuum electrodes. At the same time he was under treatment elsewhere for high blood pressure, by x ray flashes, a method in which I fail to see any special virtue, as compared with a continuous application of the rays. He also complained of

severe headache. Systemic infection from dental foci without local symptoms had not then been discovered. I had made thousands of dental radiographs in cases presenting local indications and it occurred to me to make radiographs of all the teeth to see if the headache was a reflex from an infected tooth. The radiograph showed extensive destruc-

FIG. 3.—Radiograph showing gouty tophus of the hand of a patient with pyorrhea.

tion of bone about the apices of several upper teeth. That report and the radiographs were taken by the patient to two different dentists who examined the teeth by their usual methods and pronounced them all right. The doctor did not want to hurt my feelings by telling me their report and the teeth remained untreated until two years later when he was in a serious condition at Battle Creek. Then the affected teeth were extracted and there was some improvement, but the proper treatment had been applied too late to prevent death by apoplexy at the age of fifty-six.

Another fatal case occurred just at the transition period in our knowledge of dental infection.

CASE II.—The patient, Mrs. T., complained of a lame lower first bicuspid tooth, and a radiograph showed an area of rarefaction diagnosed by the author as periapical infection. The dentist, however, thought the tooth was not infected but simply irritated by impact with the corresponding upper tooth. His treatment was not to open the tooth and make applications through the root canal but to grind the two opposing teeth. A year later a frank abscess developed causing great pain and some swelling and recurrences during a long course of treatment. Later rheumatic symptoms ensued and septic endocarditis with infarctions in the spleen, kidneys, lungs, pleura and brain. This illness lasted seven months with pain, convulsions, paralysis and complications affecting the eye, ear and nearly every other organ. All the twenty-five general and special physicians and dentists who saw her as occasion arose attributed the illness and death to dental infection.

The natural way now is for an x ray examination to be made upon the occurrence of the first

local or constitutional symptoms and for radical treatment to be applied to any dental infection revealed. I do not believe that a person is often well for years with a blind abscess of a tooth. I have known many persons who were up and about with a variety of painful if not disabling symptoms who all this time had a dental focus of infection and who got well after the latter had been discovered and treated. To my mind, this indicates not the harmlessness of such a focus but that very often the system is able to resist the infection long enough for the symptoms to be recognized and proper methods of diagnosis and treatment to be applied.

When a dentist or a physician says that the dental infection idea is often overdone, I have sometimes found on inquiry that he refers to a case in which he knows all the teeth of say a thirty-six year old woman to have been extracted. He naturally thinks that many of these were probably not infected and might better have been preserved. And that is exactly the reason for an x ray examination. The strongest reason to suspect dental infection does not afford an indication for extracting all the teeth but for locating the infected ones and acquitting the harmless and useful teeth. Another dentist may refer to the fact that the radiographer has told the patient that if the abscesses revealed had been left undiscovered and untreated some of the serious symptoms or lesions described above would probably have ensued. The dentist thinks his patient has been unduly alarmed, and it really would have been the part of wisdom, as long as the examination had been made and the trouble and its remedy discovered, to omit the list of the dangers that had been averted.

A patient, who is a great grandmother but is very active bodily and mentally, has practically all her natural teeth but has a discharging abscess of an upper bicuspid. Her dentist referred her for an x ray examination of all her teeth and many chronic infections were shown with the bone so extensively involved that several teeth could not apparently be restored to a healthy condition. Only the lower front teeth could be given a clean bill of health. On asking the patient herself whether this had affected her general health she said not at all. And

FIG. 4.—Radiograph showing marked pyorrheal destruction about one of the lower incisors.

yet she had had two strokes of paralysis, still has paralysis of the trigeminal nerve, has a bad knee for which the author applied high frequency current by vacuum electrode several years ago, and has some asthmatic trouble. Such a case and the numerous cases of arthritis or myositis causing torture or disability for years from untreated

dental infection, show how slow it is to produce death by its own poison. The more terrible cases alluded to were rapidly fatal from secondary lesions which are always to be feared. But just as the rattlesnake always gives warning, these fatal complications of dental infection are practically always preceded by signs which he who runs may read. But unlike the rattlesnake, the warning is not empty noise but some real injury, though the latter is fortunately temporary as a rule if the warning is heeded.

These patients could not be said to be well for years in spite of dental infection, the truth is manifestly that they have been ill for years. And it is my belief that if the dentist knew all about the patient, few patients with dental infection would be considered well for years.

CASE III.—An illustrative case is that of a lady about sixty years old who came a couple of years ago for dental radiography because of constitutional symptoms. A space was seen at the apex of a dead and treated tooth occupied either by pus or by a granuloma. The dentist was especially skillful and experienced in the subject of dental infection and his judgment was to leave the tooth alone as long as it did not make the patient sick. This advice was taken and for two years the patient was able to be about and to enjoy life, which was the basis for the supposition that the tooth was not causing illness. All this time, however, the indigestion continued and there was a gradual increase in the high blood pressure and the sense of fullness in the brain and the pain in the knee (with a negative radiographic appearance) and especially a gouty swelling and redness and pain in the nose. An extended series of inoculations with extracts of every conceivable article of food and drink showed no reaction to indicate that any of these caused the symptoms. Then a radiograph showed the affected tooth to be in the same condition as two years previously. It could not be cured by treatment and the dentist extracted it. A sac was adherent to the root. The symptoms including the high blood pressure were all improved immediately and the final result was that the blood pressure became normal and remained so, and the other symptoms all disappeared.

The burden of proof should not be thrown upon the patient to prove that he is actually sick and more especially to prove that his sickness is due to the infected tooth. Such a course gives the infected tooth too great an opportunity to do irrevocable harm. The burden of proof that the tooth is actually infected should not be thrown upon the patient who is manifestly ill and has a manifest periapical cavity, which might look very much the same whether it contained pus or an infected or uninfected granuloma, or who has a dead tooth from which the nerve has not been removed in whole or in part or the root of which has been only partially filled leaving a space prone to infection.

Whenever it is a question between saving the tooth and saving the patient, the latter must have the benefit of any doubt. In many cases both the patient and the tooth can be saved by the treatment of the latter. But if conditions are such that the

tooth cannot be treated and it manifestly may be a focus of infection and the patient has symptoms well known to be often due to dental infection, the patient and not the tooth should have the benefit of any doubt.

In a case of disease, say rheumatism, an x ray examination of the teeth is made not chiefly to find out the cause of the disease and a possible or probable cure; but far more to find out whether there is tooth infection which may well be a much more important matter than the symptom or lesion which has suggested its possible presence. Supposing there is an infected tooth in a case of arthritis, how are we going to prove that it is the cause? Supposing there are tubercle bacilli in a patient's sputum or diphtheria bacilli in a culture from a patient's throat, how are we going to prove that the germs are the cause of the patient's illness? Observations and experiments by the world's greatest scientists, with every hospital and laboratory facility and extending over years, were required to prove that these germs are the cause of these two diseases. To prove it in an individual case might well be impossible and even the attempt would certainly subject the patient to experiments, and delays and dangers. The usual custom is to proceed with measures of treatment and prevention of contagion just as if Koch or Klebs and Loeffler had made the actual demonstration of the causative relation in our particular patient.

There are cases where the secondary lesion is of so serious or permanent a character that no radical improvement seems to be expected from the discovery and cure of the primary cause. Even here an infected tooth is not a benefit to the patient, and is a very probable cause of still more painful and serious lesions and of nonsuccess of remedial measures.

Dental infection sometimes shows how severe it has been by the reaction which ensues where the tooth is extracted or the abscess opened into through the root canal. This is a reason for not initiating treatment of more than one or two foci at once.

When the dental infection is the cause of the symptoms or lesions an immediate cure is not always to be expected. A condition of the system which has lasted for years may not instantly respond to the removal of the cause, though the ultimate result may be perfect. In fact, if there is instant benefit the patient had better be warned that this may be temporary and that lasting benefit may come gradually.

Pyorrhoea.—This is practically always known to the patient and the dentist. In England it is considered to be the most common cause of arthritis. No x ray examination is required to detect its presence. It is only necessary to realize that it can cause the same troubles as a blind abscess and that the primary infection is controllable by treatment in most cases and immediately cured by extraction in the most advanced cases. Fig. 3 shows a large gouty tophus on a man's hand and Fig. 4 marked pyorrhoeal destruction about one of his lower incisor teeth.

Even without any belief in the causative relation and regarding it merely as a coincidence that

dental abscesses and other dental infections are frequently found on x ray examination in cases of arthritis and a good many other diseases, no one but a Christian Scientist would for a moment doubt the desirability of discovering and curing a dental infection.

Coming now to Christian Scientists, the author has explained to them that whether from an error or from a physical cause over which the mind has no control, carious cavities develop in teeth which only the dentist's tool can clean out and which only filling with suitable physical substance can protect from further decay and infection. When germs have passed through the exposed canaliculi or pores of the tooth substance like water through a filter, they often cause putrefaction of the dead nerve just as germs cause putrefaction of dead animal or vegetable substances entirely outside the human body. In the latter case we know that toxins or poisonous substances are produced which will injure or kill animals absorbing them, and when we see twenty-three persons out of a cooking class of twenty-seven die after eating from the same supply of canned string beans containing, as subsequent analysis disclosed, the *Bacillus botulinus*, we cannot avoid the conclusion that it was a grave error for them to eat the infected vegetable matter. Whatever the best treatment for the resulting poison common prudence would prompt the scientist, no less than the nonbeliever, to sterilize the home made canned beans by the physical agency of boiling before eating them and so avoid the poisoning.

A putrescent tooth pulp has been shown by animal experiment to contain germs and toxins which will cause in animals the various lesions and symptoms which occur in human beings with dental infection. The putrescent tooth pulp is in a cavity with hard walls which can neither collapse and so obliterate nor produce granulation or cure itself by any other natural process whether under influence of the mind or not. Like dislocation of the shoulder it is a physical condition which, with our present knowledge, cannot be cured without the use of physical agents. Whatever may be the treatment of a burn, common prudence would suggest to the scientist no less than to the unbeliever the un wisdom of cleaning gloves with gasoline near an open fire. Common prudence would indicate the un wisdom of allowing to remain undiscovered and unremoved a physical cause for trouble. No matter what one's belief might be he would not leave on the surface of the body a quantity of acid or caustic alkali accidentally spattered there but would promptly wash it off. He would remove the physical cause of trouble as soon as possible, regardless of his belief and regardless of the treatment to be adopted for the resulting burn.

I am not a Christian Scientist and do not believe they are able to help every sufferer, and it is my belief that this is one of the cases where the aid of physical agents is required. The fact of our present dependence in some cases upon physical agents is illustrated by the case of air, water and food, without which life itself ceases.

850 SEVENTH AVENUE.

THE RELATIONSHIP OF THE ANEMIAS TO LIFE INSURANCE*

BY H. Z. GIFFIN, M. D.,

Rochester, Minn.,

Division of Medicine, Mayo Clinic.

The general mortality in this country, according to the Mortality Statistics of the Department of Commerce for 1916, was approximately 1,400 for every 100,000 population. In these statistics no attempt has been made to differentiate the various types of anemia. Under the headings anemia and chlorosis are combined evidently the many types of primary and secondary anemia, with the exception of leucemia which is considered separately. Two of every 100,000 persons are reported to have died of leucemia. The death rate in 100,000 for the various forms of anemia was 5.3. Peptic ulcer is reported to have caused death in 4.6 in 100,000 persons and biliary calculi in 3.4 in 100,000. It appears then that with respect to mortality the various forms of anemia, leucemia and diseases of the spleen (7.5 in 100,000) are equal in importance to ulcer and biliary calculi combined (8 in 100,000).

One death in 700 deaths is attributed to leucemia. This disease is less common in rural districts than in cities; for instance, in Massachusetts, in cities of more than 10,000 population the rate is 2.3 in 100,000, in the rural districts 1.2. There seems to be little variation throughout the United States; the rate for Kentucky, however, is low (1.1 in 100,000 in cities and 1.2 in the rural districts). With such a definite difference the question of diagnosis in this state naturally arises. The total number of deaths attributed to leucemia in the registration area of the United States was 1424, of which males predominated (males 876; females 548). There seems to be a gradual increase in the number of deaths attributed to leucemia up to the ages between fifty and fifty-four. There is not a great variation, however, in the death rates during any period between the ages of forty-five and sixty-four. At all ages approximately twice as many cases in males as in females are reported. Leucemia seems to be a rare disease among the colored race.

One death in approximately three hundred deaths is attributed to some form of severe anemia. Throughout the registration area for 1916, 3785 deaths were attributed to anemia, the number in females exceeding that in males; females 2,101; males, 1,684. The number of deaths attributable to the anemias shows a marked variation in different portions of the country. In general, there is less anemia in the rural districts. Massachusetts has approximately equal distribution (6.8 in 100,000 in cities and 6.9 in rural districts). Kentucky again shows a wide difference, especially among the colored race (for the colored race 12.6 in cities and 2.8 in rural districts; for the white race 6.1 in cities and 2.0 in rural districts.) The average for the United States is 5.3 in 100,000. The question of diagnosis is so involved with respect to the anemias that very few deductions can be drawn from these statistics.

* Presented before the Medical Section of the American Life Convention, March 11, 1920, French Lick, Indiana.

In the medicoactuarial mortality investigation I have found no report on pernicious anemia alone. From 0.3 to 0.8 per cent. of the total number of deaths, with variation according to the age of entry, are attributed to anemia and chlorosis. For applicants between the ages of fifteen and twenty-nine, 0.3 per cent. of the total number of deaths are attributed to some form of anemia; for applicants between the ages of thirty and forty-four 0.8 per cent.; and for applicants at the age of forty-five or more, 0.7 per cent.

I have not been able to find in the literature a discussion of the relationship of diseases of the blood and spleen to life insurance. The question has been regarded evidently of little importance for two reasons: First, the total number of deaths from any one disease of the group is small, with the exception of pernicious anemia, and second, the insurance companies have not accepted applicants who were anemic or who were reported to have a large spleen or to have been splenectomized. This is, of course, a very safe attitude from the viewpoint of the insurance company, but is likely to be unjust from the viewpoint of the individual applicant. Much inconvenience, worry, and a definite financial loss are occasionally due to rejection for life insurance. I believe that the medical departments of life insurance companies should give a very full consideration to the applicants who may be rejected in order that they do not receive false impressions of their condition.

It is possible to state definitely that several types of anemias are curable: 1, Secondary anemias, which are due to hemorrhage, in which the cause of hemorrhage is benign and can be eliminated entirely; 2, secondary types of anemia which are dietetic in origin or due to hysterical dysphagia; 3, splenic anemias in which an exploration at the time of operation shows no evidence of cirrhosis of the liver, portal or splenic thrombosis, or gallbladder disease, and for which a splenectomy results in satisfactory convalescence; and 4, anemias which are associated with the clinical entity, hemolytic jaundice, after the patient has satisfactorily recovered from splenectomy.

Pernicious anemia.—J. W. Fisher, of the Northwestern Mutual Life Insurance Company, has furnished me with information concerning claims paid in cases of death due to pernicious anemia. In 1919, thirty-six of a total of 4,234 deaths from all causes were from pernicious anemia; this is .85 per cent. None of the thirty-six patients had been listed on the books less than three years, and the average duration of their insurance was nineteen and six tenths years. Of a total of 18,878 deaths from all causes in persons insured by this company during the last five years, 191 were ascribed to pernicious anemia, approximately 1 per cent.

F. H. Rockwell, of the Equitable Life Assurance Society, found in reviewing his statistical material that 172 of 27,784 deaths, from May 1, 1917, to Jan. 31, 1920, were due to pernicious anemia. This is a percentage of 0.6. The policies of these persons had been in force less than five years in only 5.2 per cent.

N. W. Muhlberg, of the Union Central Life Insurance Company, has furnished me with the statistics of this company. For the five-year period 1915 to 1919 there were 7,474 deaths, of which seventy-three were attributed to pernicious anemia, a percentage of .97.

The statistics of the Northwestern National Life Insurance Company furnished by H. W. Cook for the years 1915 to 1919 show seventeen deaths of 1,589 from pernicious anemia, a percentage of 1.06.

The statistics of these insurance companies may be compared with the general mortality statistics of one death in three hundred ascribed to anemias. The statistics of the insurance companies show approximately three times as many deaths from pernicious anemia as those of the Department of Commerce. This may be explained by the fact that the cause of death in insured persons is always carefully investigated by the companies, while many deaths from pernicious anemia are undoubtedly listed under other conditions in the general mortality statistics. It is likely that the actual death rate from pernicious anemia is about one for each one hundred deaths rather than one for each three hundred deaths.

Dr. Fisher states that his company does not issue insurance to persons suffering from anemia in any form and consequently special examinations of the blood are not required. Evidently insurance companies in general assume this attitude with respect to applicants with severe anemia, and so far as pernicious anemia is concerned it is very proper. Of all patients with a severe grade of anemia the smaller proportion are those suffering from pernicious anemia. Applicants with severe anemia undoubtedly should not be accepted for life insurance. It seems no more than just, however, to reconsider their applications for insurance after a period of four years. The average life of persons with pernicious anemia is less than two and one half years; occasionally patients have been reported to have lived for longer periods; a few for twelve years and longer are on record. An examination of the blood smear in the laboratory of the medical director would be a protection to the insurance company. The smears, in cases of pernicious anemia, show many large red cells which stain rather deeply, as well as deformed cells and cells with polychromatophilic degeneration. These characteristic findings, especially if associated with normoblasts or megaloblasts, would be sufficient evidence for the rejection of the applicant. Patients with secondary types of anemia, which are in many instances entirely recoverable, present a blood smear showing rather small, pale red cells without the presence of abnormal marrow cells. Two features occur almost constantly in the history of patients with pernicious anemia; recurrent attacks of glossitis with the gradual development of a shiny glistening tongue, devoid of papillæ, and the complaint of numbness, tingling, and other paresthesias in the hands and feet. These neurological complaints are the result of the cord changes which are present to a certain degree in eighty-five per cent. of the cases. Applicants with blood smears characteristic of the secondary types of anemia could be advised to seek

diagnosis and treatment by a competent clinician, and to reapply for insurance in from two to four years.

Leucemia.—In the Northwestern Mutual Life Insurance Company five of 4,234 deaths from all causes in 1919 were attributed to leucemia, approximately 0.1 per cent. During a five year period among 18,878 deaths from all causes 0.2 per cent. were due to leucemia. In the year 1919 there was only one death from leucemia during the members' first year of insurance, and this seems to have been a case of acute leucemia with an illness of very short duration. The five applicants who died had been insured in the company on an average of ten and six tenths years.

A review of the statistics of the Equitable Life Assurance Society shows eighty-four out of 27,784 deaths to be due to leucemia, a percentage of 0.3; of the Union Central Life Insurance Company, ten of 7,474 deaths, a percentage of 0.13. L. F. Mackenzie, of the Prudential Insurance Company, has furnished me with statistics on industrial insurance from which I calculate a percentage of 0.12 for deaths due to leucemia.

It is evident from these statistics that in a company with a well organized medical department leucemia is a disease which demands little special attention. It is conceivable that a patient with leucemia might occasionally be accepted by mistake as a life insurance risk. I have seen at least half a dozen cases in which the patients were not anemic and the diagnosis was made as the result of a blood count taken because of the presence of spleens which were barely palpable and might easily have been overlooked. The patients themselves came with complaints of a neurotic nature. There is no means of excluding this group of mistakes, however, without very careful clinical study, but in such cases the blood smear would disclose definite evidence of the disease.

Secondary types of anemia.—I would like to draw your attention especially to the types of secondary anemia from which patients may definitely recover and because of which it would apparently be an injustice to deny an applicant the privilege of obtaining insurance at some later date. We have been surprised to find that very severe anemias may result from slight and at times almost unrecognizable bleeding from hemorrhoids which may have lasted for two or three years without evidence of anemia. Finally, however, the hemopoietic organs fail to respond to the demand placed on them; and under these circumstances a very slight hemorrhage is sufficient to maintain a severe grade of anemia. In fact, the organism may be said to develop the "anemia habit," so that at the time the patient is examined a marked anemia may be present without hemorrhage. Patients who have developed the so-called anemia habit usually require one transfusion, after which the blood improves with medical treatment. Proper operative measures for the hemorrhoids obviate the possibility of further bleeding and the patient is permanently cured.

Secondary types of anemia due to profuse menstruation over a period of years are similarly re-

coverable. The increase in the number of policies issued to women makes this a noteworthy consideration. It is not necessary that uterine bleeding should be excessive to result eventually in a severe grade of anemia. If anemia is due to a hypertrophic endometritis, it can usually be checked permanently by means of radium. Removal of a benign polyp is also frequently necessary. An improvement in the condition of the blood will occur and within one year or, at the most, two years a reapplication for insurance should be acceptable.

Applicants with severe anemia due to obscure bleeding from ulcer of the duodenum should have the same consideration that is given to applicants with duodenal ulcer when an operative cure has been effected.

Dietetic anemias of adults have not received the attention they deserve. An improperly balanced diet, especially one low in protein or green vegetables, may result in severe secondary anemia. In addition to these simple forms of dietetic anemia H. S. Plummer has demonstrated a new clinical syndrome, of which the cardinal clinical features are anemia, very slight enlargement of the spleen, and a hysterical block of the upper end of the esophagus. Patients with this condition frequently choke on pills and certain kinds of food, especially meat. They consequently avoid foods which cannot be finely divided. After the passage of an olive, regardless of its size, they are able to eat normally. Following this the anemia promptly improves, the spleen becomes normal in size, and the patient completely recovers.

Applicants for insurance who may be shown to have severe secondary types of anemia due to such conditions as hemorrhage from hemorrhoids, profuse menstruation, and hysterical dysphagia should, it seems to me, be allowed the privilege of reapplication two or three years later when a sufficient length of time has elapsed to permit recovery in favorable cases.

The medical examiner must constantly be on guard in order that he may not overlook the simple anemia of such serious diseases as tuberculosis, nephritis, and cancer. It is very well known that even moderately severe grades of anemia may be difficult of recognition on inspection alone. In fact the use of the Tallquist scale should be required in the examination of every applicant. Special mention should be made of the severe degree of anemia which sometimes occurs in association with carcinoma of the fundus of the stomach, and also of the colon, especially of the cecum and ascending colon. Indeed the diagnosis of cancer of the colon in these cases may be reached with extreme difficulty.

Splenic anemia.—Applicants who have had splenic anemia should be considered for acceptance when all other conditions that may simulate splenic anemia have been excluded, if cirrhosis of the liver and portal or splenic thrombosis were not demonstrated at the time of splenectomy, provided that recovery has been prompt and the person has been well for a period of four or five years. Splenomegaly in simple splenic anemia occurs with a pure-

ly secondary type of anemia which in many instances is associated with, and probably the result of, gastro-intestinal hemorrhages caused by the engorgement of splenogastric vessels. Patients with uncomplicated splenic anemia who survive operation are cured. In our series of seventy-one cases of splenic anemia in which splenectomy was performed, thirty-two were found to be uncomplicated cases; portal cirrhosis and ascites were not present, the exploration of the gallbladder was negative, and there was no evidence of splenic thrombosis. In thirty of the thirty-two uncomplicated cases the patients recovered following operation, and all, so far as can be ascertained, are well.

Hemolytic jaundice.—The cure of hemolytic jaundice by splenectomy is one of the conspicuous therapeutic triumphs in diseases of the hemopoietic system. Hemolytic jaundice is a rare disease with distinctive clinical characteristics. Elliott and Kanaavel in their very careful review of the literature (1915) collected forty-seven cases (one case of their own) in which splenectomy had been done. In 1917 I reviewed the cases of seventeen patients splenectomized at the Mayo Clinic. Since then fifteen more patients have been examined, making a total of seventy-nine. The actual incidence of the disease is difficult to determine. We have observed approximately fifty cases (medical and surgical) in five years, or ten cases each year among fifty thousand or more patients. This incidence, therefore, is about one in five thousand patients. The results following splenectomy were uniformly good; recovery was prompt and permanent. In every instance in which the diagnosis of hemolytic jaundice was indisputable the patient was cured if he survived the operation.

There is, however, one exception to this general rule: A patient who has had hemolytic jaundice for many years may develop anemia in which the blood picture of pernicious anemia is simulated, at least a blood count of high color index (1+). In this type of case the anemia may persist to a certain degree after splenectomy.

The first splenectomy for hemolytic jaundice was performed by Spencer Wells in 1887; Dawson, in 1914, twenty-seven years later, reported this patient to be cured. Bland-Sutton operated on a patient in 1895. Ten years later this patient was well. Banti, in 1903, operated on a patient who was reported cured eight years later. The first patient operated on at the Mayo Clinic is now in excellent health, nine years after the operation. The clinic's experience in a series of thirty-two splenectomies for hemolytic jaundice has demonstrated remarkable results. There is no doubt in the minds of surgeons and physicians in general who observe the remarkable improvement in the condition of patients who have been splenectomized for hemolytic jaundice, that some very important factor is either neutralized, removed, or so influenced that a cure results. It is impossible at present to determine life expectancy for applicants for life insurance who have had splenectomy for hemolytic jaundice. However, they may at least be entitled to consideration for term insurance at a special rate, and indeed could be safely granted a more liberal form of policy.

SUMMARY.

1. The increase in the incidence of pernicious anemia makes it advisable to consider this disease separately in mortality statistics, rather than to include it among anemias in general.

2. Medical examiners should be required to report a hemoglobin estimation of each applicant (the use of a simple scale would be sufficient). Blood smears forwarded to the laboratory of the central offices by examining physicians would be of great assistance in eliminating for insurance applicants with pernicious anemia and leucemia.

3. The refusal of all applicants with anemia without a definite understanding concerning the possibility of later reapplication and acceptance may be a serious injustice to the individual.

4. Applicants with anemia from chronic recurrent hemorrhage, anemia from insufficiencies of diet, or as a result of functional dysphagia, may be expected to recover within one year at most after proper treatment, and should be given the privilege of reapplication at a subsequent time.

5. Applicants who have had splenectomy for splenic anemia, provided cirrhosis of the liver, gallbladder disease, and thrombosis of splenic vessels are not present, might be considered acceptable risks for term insurance after having been well for five years following operation.

6. Applicants who have recovered following splenectomy for hemolytic jaundice may safely be considered for a more liberal form of policy if they have remained well for five years.

Râles after Expiration and Cough as a Means to Early Diagnosis in Tuberculosis.—B. L. Taliaferro (*Virginia Medical Monthly*, January, 1920) has the patient breathe out, cough, and quickly breathe in. Râles not heard on ordinary or deep breathing are often thus elicited. Where the patient is unable to carry out what is required of him, the author demonstrates the procedure himself. The patient is told to cover the mouth with a gauze handkerchief, imagine that it is a window pane on a cold morning, blow the breath out as fast as possible, next give a quick hack or cough into the gauze, immediately take a fairly deep breath, and repeat the process each time the examiner moves the stethoscope.

CLINICAL SIGNIFICANCE OF CARDIAC MURMURS.*

By FRANK A. JONES, M. D.,
Memphis, Tenn.

The English school has been and is still the leader in the study of cardiac diseases. Since the days of Walsh and Corrigan down to the present time, with such men as MacKenzie and Lewis, there has been a gradual evolution and change regarding the value of the presence of a murmur in studying heart disease. In presenting this paper I shall not attempt to review the literature nor add anything specially new. The object of the paper is to present the subject matter in such a way as to be of benefit to both the specialist and the general practitioner. As a teacher of physical diagnosis in the hospital wards, in the amphitheatre and in the out clinic for more than twenty years I have reached some definite conclusions. Perhaps some of them may seem radical.

The question naturally arises, especially where the clinician has had a broad experience in observing diseases of the heart, when is a murmur of value in making a diagnosis? When is it significant and when is it to be dismissed in making a diagnostic estimate? In my consultation work I have been much impressed with the fact that entirely too much value has been attached to the presence of this mystic something we are pleased to call murmur.

Too often incorrect diagnoses are made, improper treatment is instituted and many subjects made introspective. Do not attach too much importance to finding a murmur. If you go back to the days of Corrigan and Walsh and in this country to the time of Da Costa and Flint, you will observe that all hinged upon the location, the time and quality of the murmur, that the diagnosis, prognosis and treatment rested almost entirely upon the stethoscopic findings. Fortunately that day is passing, but it has not passed rapidly enough. Let us go back to our college days, say thirty or thirty five years ago and remember what we were taught. The classification of murmurs hitherto has been burdensome. We have been told about endocardial murmurs, extracardial murmurs, cardiorespiratory murmurs, dynamic murmurs, anemic murmurs, accidental murmurs and others. There is no classification that is really satisfactory, but in time we trust cardiologists will reach a standard as to classification. For a working basis MacKenzie has classified murmurs as physiological, functional and organic.

In studying cardiac affections I wish to impress upon you that the presence of a murmur is the least important of all of our findings. It does not matter whether the murmur is physiological, functional or organic. Perhaps the question might arise in the minds of some, can we have a murmur where the heart is perfectly normal? Can we have a functional murmur when there is no evidence of organic disease? Can we have an organic murmur in which the prognosis is good and in which case the patient may live out his allotted time and die from some intercurrent trouble? All these questions can be readily answered in the affirmative. Perhaps some

may ask what we mean by a physiological murmur. We are able to answer this question by citing the presence of a murmur in young adults in whom there has been no history of previous infection; where the patient is in the pink of health, and is not conscious of the presence of a murmur until informed by the physician. These physiological murmurs have their analogue in the high pitch respiration so frequently found particularly over the apex of the right lung in children and young adults. The question of physiological murmurs in young people perhaps is a question of biology, biochemistry; a physiological, anatomical, histological, embryological question. In proportion to the degree that the arteries, myocardium and valves develop into maturity the murmur will disappear.

We are hearing a great deal today about functional tests. The whole medical world has turned on its head with reference to functional activity, to the detriment of pathology. When we use the term functional murmur the thought intrudes itself as to its nature. In truth it seems that functional murmurs in a measure, in many instances can be used as a synonym of physiological murmurs. In other words if we test out carefully through a system of exercise the heart muscle, estimate the size and condition of the heart by palpation and auscultation and find everything working well, for the want of a better term we can use the generic term, functional murmur. I have been accustomed to classify these physiological and functional murmurs as benign in that they are of but little importance and have slight bearing on the cardiac state.

It will not be necessary to dwell upon organic murmurs except to say that when found, the history of the case together with other physical findings will place the value of a murmur where it belongs.

Graham Steele, another eminent English cardiologist, has said: "No one ever dies from mitral regurgitation." He stated that when the heart failed where there was a mitral systolic murmur present, heart failure had occurred, not because of the regurgitation, but because there were present other factors which provoked it, such as some myocardial disease or impairment. "This was so opposed to the conception of heart failure by back pressure which I had been taught to accept that I carefully observed my patients to see whether or not it was true; and now I can fully endorse Graham Steele's diction."—MacKenzie. What Graham Steele has said about mitral lesions can as well be said about aortic lesions. Hitherto we have laid too much stress on the term and diagnosis valvular lesion. How often do we see death certificates signed, "organic valvular lesion of the heart." In any given case of heart disease the results of previous infections, whether the condition be of long duration and chronic or acute, the condition at the valve has but little to do with the death of the patient. In other words the valve lesion *per se* is merely a part of the general pathological cardiac condition. MacKenzie has well said in any infection of the heart no one tissue is absolutely attacked. The infection frequently spends its force on the entire cardiac structure, namely valvulitis, endocarditis, pericarditis, myocarditis blended to make the sum

*Read before the Mississippi State Medical Association, May 12, 1920.

total of the cardiac pathological condition carditis. Our whole attention must be directed in the management of any given case to the heart muscle and its sac, the pericardium, and its lining membrane, the endocardium. From our accumulative knowledge of cardiac disease where there is a pathological condition in the valves associated with changes taking place in the cardiac structure, when compensation fails, we can use the hyphenated term, myocardial valvular insufficiency. Reverting to the clinical significance of cardiac murmurs their only significance is determining what valve is affected, if organic; how much enlargement there is of the heart; what symptoms are present; the nature of the infections that lead to the valvular defect; the age and general nervous makeup of the patient.

Given a case we will say of mitral insufficiency the result of rheumatic endocarditis, in either adult or child, if we find a systolic murmur at the apex possibly not transmitted further than the axillary line, with the apex beat in the normal line, the apex beat not diffusible nor tumultuous, with the pulse normal, the pulmonic second sound not markedly accentuated, with no symptoms of dyspnea, no enlargement of the liver, nor evidence of stasis anywhere, we can assure the patient that the condition is of but little moment and not to be regarded with too much disquietude. It is well in this type of case to put the patient through a strenuous gymnastic exercise and test the heart after the exercise to estimate the reserved integrity of the heart muscle. Where the heart responds and shows no evidence of a weak myocardium, making this demonstration to the patient is quite often a valuable aid in reassuring him that his condition is not serious. A great many of these patients come to me either with strychnine tablets or with tincture of digitalis. In such cases giving strychnine and digitalis or any cardiac tonic or stimulant is like handicapping a well bred race horse on a smooth track. How often have I seen these patients' nervous systems tuned to high C by the strychnine they are taking and the heart muscle made irritable by the injudicious use of digitalis. In such cases there is no indication whatsoever for medical agencies. The psychic condition needs more treatment and attention than the heart needs medicine. Too often these patients are put to bed to take rest treatment without due consideration and weighing all the evidence. They become markedly introspective while in bed and are constantly watching the heart. Exercise and mental diversion are what they need and not rest.

Now as to physiological murmurs, they are nearly always systolic in time and at the apex. They may be distributed over the entire precordium. The heart is never enlarged and the history as to infection is nearly always negative. There is not much area of transmission; the heart responds to all tests. These physiological murmurs are too often confused with the true organic mitral regurgitation, merely by the findings of a systolic apex murmur. A careful physical examination of the patient, however, can easily decide the question in many instances. The late war has taught us some valuable lessons with reference to cardiac diagnosis. Some of the long accepted views have been reversed. Since the war

I have examined numbers of patients coming out of base hospitals with a diagnosis of mitral regurgitation, when upon a most searching stripped examination and a thorough review of their history I could find nothing to justify the diagnosis except a slight systolic whiff at the apex. I am quite satisfied that numbers of men on examining boards making these examinations were young amateurs, who had not been sufficiently trained in physical diagnosis. I quite agree with MacKenzie when he says, "Perfectly healthy men have been rejected from the army, or invalidated out of it, because a murmur was detected in their hearts. Others who present themselves for life insurance are rejected or made to pay a higher premium for the same reason, while innumerable individuals are subjected to prolonged treatment and great restrictions in their mode of life because these early superficial observations have misled the profession." The question of life insurance in its relation to heart murmurs concerns all medical examiners. Were I the chief medical examiner of any life insurance company the detecting of a murmur without other findings would not deter me from issuing a policy without extra premium.

Diastolic murmurs are practically always organic. Just why this is true no cardiologist has yet been able to give a reason. We have for a working basis but two diastolic murmurs of consequence, namely, that of aortic insufficiency and the late diastolic murmur of mitral stenosis. So far as I am personally concerned I have never been convinced, from the quality of the murmur upon auscultation in mitral stenosis, that it is diastolic. Personally, I am content to classify the murmur so typical and characteristic in mitral stenosis as presystolic. I have been much amused of late in reading the superabundance of literature upon the subject in army and base hospitals as to the question of this lesion. I read an article not long since in which the statement was made that the author did not consider the presystolic murmur of any consequence, that he had discarded its significance, and that it was not considered at all in a diagnosis of mitral stenosis. I do not think that any cardiologist of broad experience can accept this dictum. In fact, the presystolic murmur, or as some call it the late diastolic murmur, is as characteristic of mitral stenosis as the diastolic murmur is of aortic insufficiency. Personally, I would not be satisfied with the diagnosis, particularly where there is perfect compensation, without the presence of this distinctive murmur. In fact, the presystolic thrill over the apex on palpation and the presystolic murmur on auscultation clinch the diagnosis. In aortic insufficiency, whether endocardial or arteriosclerotic, the diastolic murmur at the base is just as distinctive as the presystolic murmur at the apex in mitral stenosis.

In conclusion, let us remember that in organic cardiac lesions the finding of a murmur is merely an aid to the diagnosis and is to be considered as the least important of all of our findings; that physiological and functional murmurs are of but little consequence and must not be confused with organic murmurs. Let us be careful and painstaking in history taking and in a thorough physical examination of the patient in making any estimate.

FISSURE FRACTURE OF THE TIBIA.

*With Reports of Cases.*BY JACOB GROSSMAN, M. D.,
New York,Chief of the Orthopedic Clinic, Lebanon Hospital; Chief of the
Orthopedic Clinic, Stuyvesant Polyclinic; Instructor of Ortho-
pedics, New York Postgraduate Medical School.

Fissure fracture, also known as subperiosteal, intraperiosteal, linear and oblique fracture, is one in which the bone breaks or cracks inside the thick periosteum, as a willow bough cracks without tearing its bark. The commonest site of this type of fracture is in the tibia. Only one was found elsewhere and that was in the fibula. This case was reported by me (1) in 1916. Fissure fracture is especially found in children and results from direct trauma, such as a falling object striking the leg, or a fall striking upon the leg.

ETIOLOGY

In this series there were twenty-one cases. Of these sixteen or eighty per cent. were in males and five or twenty per cent. in females. Ten were in the left tibia and eleven in the right. Nineteen or almost ninety-five per cent. occurred in children who were below ten years of age. One occurred in a boy of thirteen and the other in a boy of fifteen. The youngest child was twelve months of age. The commonest cause was a fall, the patient striking upon the affected leg. The distance of the fall varied. In some instances the patient fell from a high chair, in others down the stairs, a distance of one or two steps, in others they fell on level ground. In a number of instances the trauma was very mild.

SYMPTOMATOLOGY

The subjective symptoms varied from mild cases to very severe ones. In some instances the pain and disability were slight. The pain was especially evident when the child attempted to walk or when the affected limb was manipulated. The subjective symptoms in a number of instances were so mild that the mothers were surprised to learn of the presence of a fracture. In others the pain and disability were so severe that the patients refused to walk and would not permit the slightest manipulation of the affected leg. Disability was marked.

The diagnostic objective symptom is pencil tenderness. It is excruciating in character and can be mapped out by means of the rubber tip of a pencil, which is made to exert pressure over the area of trauma. The line of fracture can be traced by this means in a large number of instances. This symptom may persist for months. There may be slight swelling and ecchymosis around the site of fracture. A limp on the affected side was usually present. Crepitus, false mobility and deformity were always lacking.

DIAGNOSIS

The diagnosis is usually made by mapping out the pencil tenderness and confirmed by subsequent x ray pictures. It is essential that the x ray pictures be taken in several planes as the fracture may show in one plane only. This plane, as has often been the case, may be omitted, and the fracture may be overlooked.

In sprains and contusions the tenderness is as a rule more generalized than it is in fissure fractures. There are no areas of pencil tenderness in the former conditions. Tenderness and pain in sprains and contusions do not persist for as long a period of time as they do in fracture.

In one of our cases the fissure fracture was accompanied by a luetic osteoperiostitis of the tibia. The luetic infection was responsible for the persistence of the symptoms for months after the injury had been sustained. The history of the case in point follows:

CASE I.—The patient was a boy, ten years of age, who had met with an accident in which his leg was injured. He was taken to a clinic where a diagnosis of fracture of the tibia was made and proper treatment instituted. His leg was encased in plaster of Paris bandages and maintained in this fashion for several weeks. In spite of this immobilization the pain persisted. He came to our clinic several months later complaining of pain and a limp. Examination disclosed slight swelling about the centre of the shaft of the tibia. Tenderness in the same region was marked and localized. Ecchymosis, crepitus, false mobility and deformity were lacking.

It was quite evident that something beside the old injury was responsible for the symptoms. Examination of the eyes disclosed that the pupils were unequal and irregular, responding rather sluggishly to light. The teeth showed humpy molars, dental interspacing and fluting (Roberts). These latter findings suggested a possible luetic infection. Closer questioning of the mother disclosed the history of a primary infection about the time that the patient was four months of age. As she nursed the child at the time the infection was traced to that source. Subsequent blood examinations of both child and mother were made and the Wassermann was four plus. An x ray picture of the affected leg was taken and it showed an old fissure fracture and a syphilitic osteoperiostitis of the tibia.

The subsequent course of the case under treatment further confirmed our findings. The pain and disability disappeared under mixed treatment. This case is mentioned to emphasize the necessity of bearing in mind the possibility of lues being responsible for persistent pain and disability following an injury.

COURSE AND PROGNOSIS

The prognosis is excellent. The patient usually recovers within a few weeks. The pencil tenderness persists for an indefinite time after the pain and disability have subsided.

TREATMENT

The treatment consists of immobilization by means of plaster of Paris bandages. The bandages are retained for a period of two weeks when they are removed and baking and massage are given. The average length of treatment was four weeks.

It is unnecessary to report in detail the entire series of cases. The following six reports present the main features occurring in fissure fractures.

CASE II.—C. R., three and a half years of age. Three weeks before coming to our clinic, the child tripped and fell. She was taken to her family physician and local applications with rest were prescribed. In spite of faithfully carrying out these directions,

FIG. 1—Fissure fracture of the tibia. (Case II.)

the pain and disability persisted. It was for these symptoms that the child was referred to us.

The child was unable to walk, having been carried to the clinic by her father. Her leg was slightly swollen in the region of the tibial crest. Ecchymosis, crepitus, false mobility and deformity were lacking. There was, however, a line of pencil tenderness localized to the tibia and extending for a distance of about two inches. A diagnosis of fissure fracture of the tibia was made and a subsequent x ray picture confirmed the diagnosis (Fig. 1). The patient made an uneventful recovery.

CASE III.—M. O., seven years of age, fell striking upon his leg. He was brought to our clinic several days later, on account of pain and slight disability. The patient walked with a slight limp on the affected side. Ecchymosis, false mobility and deformity were lacking. There was slight swelling over the affected area. Pencil tenderness extending for a distance of about three inches was traced along the tibia. A diagnosis of fissure fracture was made and a subsequent x ray picture confirmed the diagnosis (Fig. 2).

CASE IV.—J. F., three years of age. A few days before being brought to the orthopedic clinic of Lebanon Hospital, the patient fell, striking upon his left leg. No attention was paid to the accident as he was able to get about. For the following few days the child complained of pain especially evident when he walked. The patient walked with a slight limp on the left side. The leg was swollen, there was no deformity, ecchymosis, crepitus or false mobility. A line of pencil tenderness was traced along the shaft of the tibia for a distance of two and

a half inches. A diagnosis of fissure fracture of the tibia was made and proper treatment instituted. A subsequent x ray picture confirmed the diagnosis. The patient made an uneventful recovery.

CASE V.—S. R., eight years of age, fell, striking upon his left leg. Complained of pain and a limp. There was slight swelling and ecchymosis over the upper part of the leg. Crepitus, false mobility and deformity were lacking. A line of pencil tenderness was traced for about two inches, along the upper part of the tibia. A diagnosis of fissure fracture of the tibia was made and a subsequent x ray picture confirmed the diagnosis. The patient made an uneventful recovery.

CASE VI.—H. S., fifteen years of age. About five weeks before coming to our clinic, the patient fell and hurt his right leg. Disability and severe pain followed. Ecchymosis and swelling localized in the centre of the leg were evident. Pencil tenderness was traced along the shaft of the tibia for a distance of about three inches. A diagnosis of fissure fracture of the tibia was made and a subsequent x ray picture confirmed the diagnosis. The patient made an uneventful recovery.

CASE VII.—S. S., four years of age, fell, striking upon his right leg. For a few days thereafter he complained of pain only when walking. The mother noticed that he limped. The patient walked with a limp on the right side. There were slight swelling and ecchymosis over the lower part of the

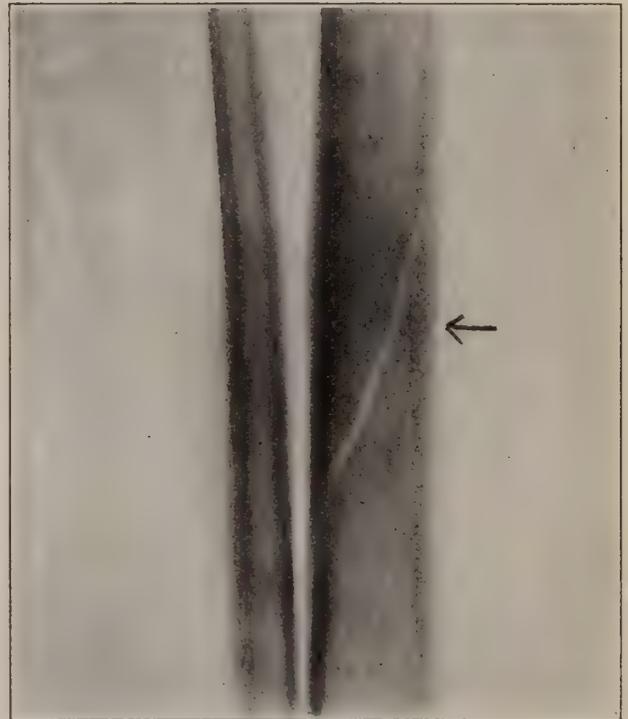

FIG. 2—Subperiosteal fissure fracture of the tibia. (Case III.)

right leg. A line of pencil tenderness was traced along the tibia for about an inch. A diagnosis of fissure fracture of the tibia was made and a subsequent x ray picture confirmed the diagnosis. This patient fell again a few weeks after he was discharged, and injured the same leg. Examination

again disclosed a fissure fracture a little higher than the previous one had been.

SUMMARY AND CONCLUSIONS:

1. Fissure fracture occurs mostly in children.
2. The tibia is usually the site of the fracture, only one case having been seen in the fibula.
3. The subjective symptoms and the disability may be mild.
4. Fissure fracture should be differentiated from sprains and contusions.
5. The presence of a luetic infection in the bone, as a factor prolonging the duration of the symptoms, should not be overlooked.
6. False mobility, crepitus and deformity are always lacking in this type of fracture.
7. The diagnostic objective symptom is pencil tenderness. It is always present and persists for an indefinite period of time after the accident has occurred.
8. The recognition of the type of fracture is important, not only from a scientific viewpoint, but also from a medicolegal viewpoint.

THE INTRAVENOUS TREATMENT OF MALARIA.

By B. S. WYATT, M. D.,
Plano, Tex.

Evolution is a law of nature. Evolution in the science and art of medicine has changed fundamentally methods of treating disease. From the primitive method of drug administration *per os* to the giving of medicine by the hypodermic syringe, was a long step forward. From the subcutaneous injection to the intramuscular injection was a logical evolution. From the intramuscular injection to the intravenous injection was inevitable. It had to come. It is here to stay. There is every argument for, no argument against intravenous therapy. Once admitted that the blood is the medium in which medicine is carried to every organ, tissue and cell of the body, there is nothing to contradict the conclusion that to introduce medicine directly into the blood is simpler, surer and even safer than to depend upon its reaching the circulating medium after having run the gauntlet of digestion, alteration, and modification by its passage along the gastrointestinal tract. There is a saving of time and effort and a prevention of imperfect action and uncertain effect.

At the present time and under modern conditions there is absolutely no logical or actual argument or objection to the intravenous method of drug administration. The work of certain pharmaceutical chemists has made possible the preparation and supply of solutions containing indicated drugs in a form entirely safe for intravenous administration. Thousands of physicians all over the world are taking up and employing the intravenous method. As the result of an extended experience I can definitely state that dangerous reactions or uncertain or negative results are conspicuous by their absence,

providing properly prepared solutions are employed. Their technic is simple, so simple, in fact, that a physician who is not qualified or able to make an intravenous injection is not qualified to practise medicine at all.

The number of physicians who depend and insist upon the intravenous method for administering iron and arsenic in anemia is steadily increasing. The same is true of the intravenous use of iodides, especially of sodium iodide. Furthermore, and as would naturally and logically be expected, the intravenous method was quickly applied to the administration of quinine in malaria. As a matter of fact, it is in malaria that the proof of the superiority of intravenous therapy over all other methods is being conclusively established.

The treatment of malaria in its various forms is by no means simple, and, if one may judge from the literature regarding it, in many cases unsatisfactory. Quinine, while it was long ago hailed as a specific for malaria, does not always act as such. Moreover, there is in malaria another element always present which, in a general way, may be referred to as anemia, which complicates matters, and which almost always requires careful treatment. There has been a change in recent years in the interpretation of the meaning of the classic symptoms of malaria—the chill, the fever and the sweat. These used to be attributed to the development of the plasmodium and the hatching out of a brood of plasmodia in the blood stream. Recent observations, however, go to show that at this stage the erythrocyte is hemolyzed. Hence the destruction of the erythrocyte with the resulting hemolysis is probably the cause of the reaction rather than the digestion of the protein of the plasmodium. Hemolyzed erythrocyte is known to cause serious reaction and to have even caused death. Hence, conclusion points to the resistance of the erythrocyte to the malarial plasmodium as the factor that determines the extent and severity of the malarial attack. It is known that each malarial attack is followed by evidence of great destruction of erythrocytes, followed by persistent and in many cases profound anemia. Recovery from anemia means practically recovery from malaria. Every study of malaria indicates that the destruction of the red cells and hemoglobin and the recovery from such a condition is a true index of the status and severity of infection. That this is true is indicated by the fact that arsenic, long recognized as a valuable remedy in malaria, particularly in chronic forms, owes its therapeutic value to its physiological action in preventing the destruction of the erythrocyte.

The red corpuscle is the chief actor in malaria. It is not alone the site of infection, but it is the most active agent in resisting the infection. Observers have reported favorable results in severe malarial infection from the use of salvarsan, and there has been placed on record a report in which the use of mercury was followed by beneficial results. Consequently, in the consideration of the effective treatment of malaria, it may be divided into two heads—first, the proper and most effective method of administering quinine in order to secure its maximum effect upon the malarial organism, and

second, and quite as important, the administration of iron and arsenic (iron cacodylate) in order to replenish the supply of erythrocytes and hemoglobin. One does not have to go far into medical literature before finding many references to the drawbacks and inefficiency of the administration of quinine, in malaria, by the mouth, e. g., MacGilchrist (1) declares that very little quinine is absorbed by the stomach, and that any absorption is due to the fact that quinine is a very diffusible substance.

In the attempt to get better results from quinine than are obtainable from its administration *per os*, numerous observers recommend its use by subcutaneous or intramuscular injection. Definite proof, clinical, as well as experimental, showed, however, that when a concentrated solution of a quinine salt, e. g., five or ten grains in thirty minim syringe, is injected into the muscles or under the skin, most of the quinine is precipitated at the site of the injection, and remains there for many hours. The tissues at the seat of injection are killed, giving rise to so-called abscesses and fibrous nodules, or, if the injection is made very superficially, to sloughing and ulceration.

It was, of course, inevitable that the suggestion should arise that the intravenous use of quinine in malaria would prove of great advantage. Several surgeons in the Medical Corps of the United States Navy resorted to the intravenous method and reported excellent results.

Thomson (2) made still further contributions to this important subject. He pointed out that the intravenous route for the administration of quinine in malaria was first used almost exclusively in emergency cases, especially those in which the patients were suffering from what has been termed pernicious comatose remittent malaria. He explained that the intravenous method had other advantages to recommend it; that it is the only route by which one can concentrate upon the parasite and thereby obtain the maximum effect at the optimum time. Thomson employed the twenty per cent. solution of the bihydrochloride of quinine. He concluded that the intravenous route has special advantages in the treatment of malaria during the active periods of the disease. By this means, the full quantity of quinine given can be concentrated against the parasite at the moment when it is most susceptible to such action and the maximum effect obtained.

In eighteen consecutive cases of malignant tertian malaria with remittent fever and with ring forms of *Plasmodium falciparum* present in the peripheral blood a single intravenous injection of fifteen grains of quinine bihydrochloride was sufficient to break the attack in every case. All stages of the schizogenous cycle of *Plasmodium vivax* present in the circulating blood were directly affected by the injection. The mature gametocytes of *Plasmodium vivax*, unlike those of *Plasmodium falciparum*, disappear from the peripheral blood under the direct action of quinine bihydrochloride given intravenously. In cases of benign tertian malaria, the patient's comfort will be considered without the parasite being spared if the first intravenous injection be given at the very end of a severe stage.

Subsequent intravenous injections should be timed to be given at what would have been about the beginning of the severe stage in the paroxysms next in order had the cases remained untreated.

In an original communication John C. Clark (3) of Memphis, Tenn., discusses the intravenous injection of quinine bihydrochloride and cacodylate of iron in treatment of chronic malaria. He reported his experience, both as to the results obtained and the reactions which were manifested. In fifty-seven cases of chronic malaria seen in private practice in the year 1917, 467 intravenous injections of quinine bihydrochloride in combination with cacodylate were given. The author states that he never saw a reaction which did not right itself within the time expected. The results were gratifying. Of fifty-seven patients reported, thirty-two were under treatment for forty days or more; the remaining twenty-five patients were given from one to five injections for relief only. Of the thirty-two patients, twenty-seven were kept under observation and in only two instances was there any evidence of a relapse. There was an average increase of red blood cells of 1,125,000 with a hemoglobin increase of about forty per cent. At the time treatment was discontinued, it was impossible to demonstrate the malarial organism in any form, or to detect any other evidence of malaria.

Carnot (4) commends the intravenous route as simple and not at all dangerous, when it is a question of striking quick and striking hard. He states that the sterilizing effect of the quinine is reenforced by this route.

L. Rogers (5) states that the intravenous administration of quinine in primary attacks of malaria appears to be worthy of careful trial, because a further material advantage of such intravenous administration is likely to be that dangerously large infections, which may terminate at any moment in fatal coma under oral administration of quinine, are likely to be rapidly controlled. He predicts that by this method, the present mortality from malaria should be reduced to practically nothing.

Knowles (6) asserts that the intravenous administration of quinine in concentrated solution is the quickest and surest method of immediately cutting short a febrile attack of malaria. It appears to be a perfectly safe method, and is infinitely preferable to intramuscular injections from every point of view. He declares that there is quite a sufficient amount of evidence now available to justify the routine and extensive use of quinine intravenously.

Barbary (7) reports that he has been treating malaria during the last ten months by intravenous injection. He has treated 899 patients at the military hospital at Nice, and comments most favorably on the prompt and effectual action of this route. The injections were given every third day at first and then at five day intervals. Hence, it will be appreciated that the use of quinine intravenously in the treatment of malaria has long passed the experimental stage and is coming to be regarded as the most efficient, least dangerous, and therefore, most to be preferred method. It may be assumed, however, that in the treatment of malaria, whether in the acute or chronic form, the intravenous ad-

ministration of quinine should be employed with every expectation of success, so far as any effect upon the malarial parasite is concerned. There remains, however, the element of anemia which is always present and which always demands or should demand careful treatment.

M. R. Lawson (8) shows that multiple infection of red corpuscles with young parasites is seen in all malarial infections, but is found most frequently in estivoautumnal infections. The anemia in malarial infections is explained in Lawson's opinion, by the fact that each parasite destroys several red blood cells. Reduction of hemoglobin out of proportion to the loss of red corpuscles is explained by the fact that there is always a partial loss of hemoglobin in certain of the surviving corpuscles due to parasitic action.

Deillille and his coworker (9) report that the findings in the malaria contracted by the French troops in Macedonia show a relative frequency of hemoglobinuria, indicating massive destruction of blood corpuscles, probably in the blood stream, as the first phase. This may be accompanied by hemorrhages from the mucosa.

Netter (10) reports that in thirty-seven malaria patients, the blood corpuscles displayed greater resisting powers during the malarial attacks than at other times. He queries whether it might not be possible to sustain and prolong this by other measures to combat hemolysis. The query is answered in part by Neff. He reports five cases of tertian malaria treated with arsenic intravenously. Neff states that there is room for improvement in the treatment of malaria and that the disease is often resistant to permanent cure by the administration of quinine alone. Disappearance of fever is often taken as evidence of a cure. Given rapid destruction of red blood corpuscles and marked reduction in hemoglobin, the suggestion immediately presents itself that in iron and arsenic a remedy capable of accomplishing the second indication in the treatment of malaria, viz., to overcome the anemia and restore the blood to its normal condition. It has long been known and recognized when given by the mouth in postmalarial anemia.

In view of recent clinical reports, as well as from the theoretical view point, there is every reason to expect better results in a shorter length of time when iron and arsenic are given by the intravenous route. Iron and arsenic given intravenously have been found of special value in the treatment of non-malarial anemia; e. g., Geysler (12) reports ten cases treated with a combination of iron and arsenic given intravenously, pointing out that it is possible to demonstrate a positive increase of red cells after each infection and that results occur with a certainty and rapidity that all their efforts have heretofore failed to bring about. He states that positive clinical results can be obtained by stimulating the white and red cells, providing a remedy, the pharmacological action of which is known, is administered by this direct method into the blood stream. Stern (13) reports over 100 cases treated with iron and arsenic intravenously.

PELLAGRA.

What is true of the anemia which forms such a prominent feature in malaria also holds true of pellagra, which is invariably accompanied by a diminished amount of hemoglobin and impaired resistance on the part of the erythrocyte. Recovery from pellagra is invariably associated with recovery from the anemia, which is its characteristic feature. Perhaps the main object of treatment is to increase the number, quality and resisting power of the erythrocytes, together with an increase in hemoglobin and the bringing the blood back to normal. For obvious reasons, iron and arsenic may be relied upon to do this, provided they can be introduced into the body in such a way as to enable them to exert a thorough and free physiological and therapeutic effect. This means, naturally, by the intravenous route.

Perhaps the greatest objection that has been raised to the employment of quinine, iron or arsenic, intravenously, has had to do with the difficulty and possible danger incurred in the extemporaneous preparation of solutions of these drugs for such use. Experience with the administration of salvarsan and others of this group has impressed upon the minds of many physicians the fact that

CASE I.—Tertian Malaria:

Patient had been having chills six weeks, very emaciated. Intravenous injection quinine May 25th, 26th, 27th, 28th, 29th, June 1st, 3rd, 9th, 16th, 23rd, alternating with 5 c. c. iron and arsenic solution at intervals twice a week until August 9, 1919.

May 25, 1919.
red cell count, 3,000,000
hemoglobin, 60 per cent.
white cell count, 18,000

August 27, 1919.
5,200,000
98 per cent.
6,500

CASE II.—Quotidian Type:

Intravenous injection 5 c. c. quinine every day for seven days. Alternating twice a week each with 5 c. c. iron and arsenic solution until August 7, 1919.

June 2, 1919.
red cell count, 4,500,000
hemoglobin, 70 per cent.
white cell count, 3,500

August 7, 1919.
6,180,000
95 per cent.
8,000

CASE III.—Quartan Type:

Intravenous injection every day for seven days; every other day for fourteen days alternating with iron and arsenic, 5 c. c. solution, until August 27th.

June 5, 1919.
red cell count, 3,400,000
hemoglobin, 40 per cent.
white cell count, 2,000.

August 27, 1919.
5,000,000
100 per cent.
6,000

CASE IV.—Quartan Type:

Intravenous injections 5 c. c. quinine solution every day for seven days, every other day for twelve days. Then alternating twice a week with 5 c. c. solution iron and arsenic until July 19, 1919.

June 7, 1919.
red cell count, 4,100,000
hemoglobin, 75 per cent.
white cell count, 4,000

July 19, 1919.
5,400,000
95 per cent.
7,000

CASE V.—Quartan Type:

Intravenous injection 5 c. c. quinine every day for eight days, every other day for sixteen days. Then twice a week, alternating with iron and arsenic solution 5 c. c. once a week until August 27, 1919.

June 6, 1919.
red cell count, 4,200,000
hemoglobin, 55 per cent.
white cell count, 10,000

August 27, 1919.
6,000,000
90 per cent.
6,000

unless special precautions are observed and correct technic followed, dangerous reactions are to be expected.

My experience with the intravenous method extends over a period of two years, during which time I have treated thirty-two cases of malaria. Quinine was administered in the form of a five c. c. solution containing five tenths grain of quinine bichloride. The iron and arsenic were contained in the five c. c. solution representing sixty-four mg. The number of cases treated with iron and arsenic alone and the results that I observed, justify me in stating that not alone is the intravenous method indicated in the treatment of malaria, but the results obtained lead one to conclude that the action of quinine in malaria is due to its effect upon the red corpuscle rather than to a plasmodial action. The fact that iron and arsenic stimulate an increase in the number of erythrocytes and their resistance, is well founded in medical experience. However, the prominently positive and uniform results from the intravenous administration of iron and arsenic as indicated in my experience cause me to state that this is the ideal treatment of malaria. The case histories given indicate the results I have obtained.

These cases were selected out of a total of thirty-two. Twenty-seven similar cases treated by the same method have convinced me that the action of quinine given intravenously upon the plasmodium is evident during every stage of the life cycle in man. The effect of the drug varies with the time of administration and the size of dose given. If quinine is continued, the blood being examined at regular intervals, it will be found the plasmodia diminished greatly in number up to the time of sporulation, proving that in every stage of the growth, quinine is capable of destroying them. To combat the anemia, and restore the individual to his normal tone, I have always given intravenously, five c. c. solution of iron and arsenic until hemoglobin and blood count become normal.

Treatment of Entropion.—Jacqueau (*Lyon médical*, March 25, 1920) reports a case of spasmodic entropion by the use of a Michel clamp fixed in a vertical position above the eyelid. The measure is recommended as very simple, practically painless, requiring no dressing, and giving the best results, notably in postoperative spasmodic entropion.

INTRAVENOUS MEDICATION.

BY CHARLES GREENE CUMSTON, M. D.,

Geneva, Switzerland.

Given the great interest shown in, and the considerable progress made of late in intravenous medication, I propose to offer a brief review of the subject as it stands on the Continent. It is true that many physicians are perplexed by the simple phenomena following intravenous injections of various substances, given under the names of hemoclastic crisis, peptonic or anaphylactic shock, but in order not to confuse the subject still further by discussing the differential reactions, the experimental results shall not be referred to—although many are of unquestionable interest—and, therefore, only the clinical aspects need be examined, passing in review the simplest to the most complex injectable substances with the opinions of the observers most competent in the matter.

In septicemias resulting from wounds, especially war injuries, Audain and Masmonteil have employed intravenous injections of an isotonic solution of sugar—glucose, saccharose or lactose—as a leucogenous procedure which, by increasing the number of leucocytes, heightens the organic resistance to infection. During the past year, Humbert, of Geneva, has also resorted to intravenous injections of sugar in pulmonary tuberculosis with good results.

The leucogenous action of sugar given intravenously is, in reality, quite remarkable, because within thirty minutes after the injection the leucocyte count reaches from seven to twenty-five thousand and remains at this figure for two to three hours, afterwards falling to about fifteen thousand. According to Audain and Masmonteil, the injections produce quite as marked reactions as the colloid metals, sodium nucleinate, etc. The leucogenous action manifests itself clinically shortly after the injection by a transitory rise of temperature of a few tenths of one degree, ushered in by a severe chill and followed by a sudoral crisis similar to a paroxysm of malaria. The thermic maximum corresponds with the maximal phase of hyperleucocytosis, but these phenomena are those met with following the injection of any leucogenous substance, especially when given intravenously. The phenomena of reaction are proof of leucocytic changes and are consequent upon the sudden and massive introduction of foreign bodies into the circulation.

It is not to our purpose to enter here into a discussion of the scientific aspects of the leucogenous action. Suffice it to say that intravenous injections of sugar first produce a chill, a slight rise of temperature and sudation, accompanied by leucocytosis and afterwards by a fall in the temperature, with a normal pulse rate, profuse diuresis, and an amelioration of the principal symptoms, but sometimes followed by a painless abacterial abscess. These results may be permanent, but usually the injections must be repeated several times.

In a lecture delivered at the Paris Faculty of Medicine last year on intravenous injections of peptone in infectious diseases, Professor Nolf, of Liège, pointed out the phenomena which resulted, as follows. "The immediate result depends upon the dose

injected. If it is equal to or less than one centigram for each kilogram of the patient's weight—a patient of medium build receiving from five to six c. c. of a ten per cent. peptone solution—a rise of temperature usually occurs one or two hours after the injection and lasts for several hours. If the dose is a little stronger—from seven to ten c. c. of a ten per cent. solution—the same initial rise is observed and may be ushered in by a more intense chill, the onset being usually about one hour following the injection. The chill lasts from twenty to thirty minutes and is followed by a phase of heat of 101° to 102° F., after which a phase of sudation is prone to occur. When the sweating takes place, the temperature will have already fallen a little, but continues to drop rapidly as the sudation increases, so that within three or four hours after the onset of the sweat it will have become normal or nearly so, and remains normal for some time."

The thermic drop referred to by Nolf is accompanied by a general amelioration; in typhoid fever especially, the abdominal distention, prostration, delirium, insomnia, and signs of bronchitis diminish or even disappear. It is hardly necessary to say that in two or three days the phenomena of the infectious process return, but if the injections are given every second day a marked drop in the temperature will be maintained which in itself is advantageous to the patient.

Nolf does not insist upon the leucocytic reaction, but it is known that it exists, both by experimental work and direct clinical examination of patients having received peptone injections. On the other hand, Nolf refers to certain disadvantages of the injections when they are given too often or in too large doses in profoundly infected subjects. A syndrome develops consisting of dyspnea, tachycardia, hypotension, distress, and sometimes a more or less extensive urticaria, which Nolf compares to anaphylactic shock, but which he nevertheless designates under the term of peptonic shock.

Peptonic shock is, in reality, a German invention, which was put forth by Schmidt-Muhlheim if credence is to be placed on German assertion. At all events, it has been studied in France by Gley, Hédon and especially Delezenne, the latter showing that the shock may be brought about by very different substances—toxins, vaccines, extracts of organs. But why peptonic shock, since Nolf himself admits that intravenous injections of colloidal metals give rise to similar phenomena? To this Nolf replies that the colloidal metals are stabilized with organic substances—gelatin, serum, peptone—and it is these substances and not the colloidal metals which give rise to the accidents which follow. Unfortunately this argument is not acceptable, as Laumonier justly points out, because Bredig's colloids—which contain nothing but the powdered metal and pure water—produce reactions in every point comparable to those resulting from stabilized colloids, but also to peptones and sera.

Briefly, as to the nature of peptonic shock, all that is essential to remember is that intravenous injections of peptone first give rise to a chill, then to a rise of temperature and sudation, as well as to various forms of distress, hypotension, and tachy-

cardia, grouped under the name of peptonic shock, and accompanied by a hemoclastic crisis—leucopenia, hemolysis, etc.—which shall be referred to later on; then a thermic drop and an improvement in the general symptoms lasting, in the average case, for two to three days. It is also to be observed that the peptone injected is soluble and assimilable as an ordinary food, but it is supposed to have the property of an antigen, that is to say, when injected into the organism it produces new specific antagonistic bodies, a conception whose insufficiency shall be shown later on.

Of late, serotherapy, autoserotherapy and plasmotherapy have been frequently resorted to. They have been utilized especially during the epidemic of influenza in 1918. Among these various trials, whose results are, in reality, absolutely comparable, that of Lesné, Brodin and Saint-Girons may be selected, since it is one of those which offers the broadest field for interesting consideration. It consists in intravenous injections of from fifty to two hundred and fifty c. c. (maximum dose) of blood plasma of convalescent subjects, normal subjects or even autoplasm, in patients presenting complications during influenza or typhoid. When the patient reacts, which does not always happen, the phenomena already referred to develop.

Most observers maintain that, in a general way, at the end of from fifteen to sixty minutes there is a general chill and a sensation of cold with headache. Then the rectal temperature goes up to 101° to 102° F., even to 106° F., the pulse rate at the same time increases, while the blood pressure decreases. This state lasts from twenty to forty minutes, then the chill subsides, the headache disappears, sudation takes place, and the patient has a sense of wellbeing. The temperature quickly drops below its former level and ranges around 98.6° F., where it will remain or not, according to the case. This reaction is identical with that following the injection of horse serum in septicemia. It is also like Nolf's peptone reaction and near to anaphylactic shock, whose vascular blood manifestations have been comprised under the name of hemoclastic crises by Vidal, Abrami and Brissard. It is to be remarked that Lesné, Brodin and Saint-Girons admit that their injections of plasma are in no way anaphylactic and they believe that the plasma is less toxic than the serum and is to be preferred to total blood, whose red blood corpuscles act as foreign bodies. This interpretation is, so far as it goes, exact, but should be extended to heteroplasm, as well as to autoplasm and autoserum, the mere fact of being extracts of the organism making these bodies different from living plasma from the physicochemical viewpoint.

Briefly, what is to be remembered is that intravenous injections of plasma first produce a chill, then headache and hypotension, a rise in temperature, sudation, then a drop in the temperature with general improvement of the patient's general condition of variable duration—sometimes permanent. The observers last mentioned do not seem to have specially considered the leucocytic reaction, but it exists since they regard the reaction observed after injection of plasma as similar to peptonic shock and

hemoclastic crisis, in which the blood undergoes lytic, and afterwards, hematopoietic changes.

Without referring to many other substances, such as sodium nucleinate, quinine, the newer arsenical products, specific sera, etc., and their reactions following intravenous injection, the reactions to which intravenous injections of more or less fine particles of insoluble products give rise will next receive our attention.

It is known that the colloids, Bredig's for example, are heterogenous systems formed by ultra-microscopic particles carrying an electric charge of ionic origin in stable suspension in water, and that when introduced into the veins they produce reactions identical with those already mentioned and in particular, a hematic and leucocytic reaction of high grade. In this respect the pure colloids, stabilized colloids and collobiases—which are not true colloids but suspensions of finely powdered bodies in a gummy colloid—act in exactly the same fashion. Consequently, Audain and Masmonteil could, with perfect propriety, regard the leucogenous action of sugar given intravenously as the same as that of colloidal metals. Nolf compares the reactions of intravenous injections of colloids to peptonic shock, reactions which he attributes—wrongly according to Laumonier—to the presence of stabilizing bodies. Even if these were of peptonic nature, their quantity would be too small to cause any effect from the peptone which exacts, in order to occur, from fifty centigrams to one gram of peptone to each kilogram of the weight of the subject. However, let it be said that the reactions to which the collobiases give rise are usually more severe than those produced by the colloids—stabilized or not—and this difference seems to be due to the inequality of the particles of the collobiases. Nevertheless, the phenomena of reaction are, in all cases, quite alike, whether they are colloids, collobiases, sugar, peptones, sera, or plasma.

Of the work done in the United States with emulsions of dead bacteria by Cowie, Beaven, and others I shall not speak, as you have first hand information on the subject, neither need mention be made of Drinkler and Brittingham's work with transfusion of citrated blood for the like reason. I would point out, however, that Cowie and Beaven give the name of proteinotherapy to their procedure and attribute a large part to proteinic shock—in other words to the effects of peptone. But in the former case the protein is injected in the form of normally insoluble bacterial bodies; nevertheless, both reactions and therapeutic effects are and remain quite the same.

In conclusion, I would refer to the pathogenesis of malarial paroxysms, in the light of recent studies made by Abrami and Senevet. These observers have shown that the malarial paroxysm is the consequence of a hemoclastic shock identical with that resulting from the sudden intravenous introduction of any foreign matter and especially of metallic colloids. In both cases a vasculosanguineous crisis takes place, composed of leucopenia with inversion of the leucocytic formula, rarefaction of the hematoblasts, hypercoagulability of the blood and hypotension, soon followed by chills, then fever, and finally sudation. The satellite symptoms of the paroxysm

—or of a colloidal injection—paleness, nausea, collapse and urticaria, result in reality not from specific intoxication, but from the hemoclastic crisis whose vulgar manifestations it merely expresses, and this crisis occurs under the influence of the sudden inroad of the merozoites at the time when fission of the schizont occurs. This pathogenesis of the malarial paroxysm appears to be quite logical, while clinically there is a perfect similarity between this paroxysm and the colloidal reaction.

No matter what substance is injected into the blood there always follows an identical vasculosanguineous crisis with nervous and febrile manifestations, followed by a hematic and leucocytic reaction, then a return to the normal state. It is a reaction of defense against the sudden introduction of foreign bodies into the blood. This diaphylaxis occurs no matter what foreign body enters the circulation. There is no peptonic, seric or proteinic shock, but simply a hemoclastic crisis common to all, against which the organism reacts always in the same fashion.

Intravenous injections do not always result successfully, first, because the subject may not react because he is worn out by the infectious process from which he is suffering—his diaphylaxis is abolished. Therefore, the intravenous injection is useless. Secondly, certain individuals are either very sensitive or very refractory to such bodies; consequently the reactions are very violent, even fatal at times or else they are *nil*, although the defenses of the organism are not completely inhibited. In these circumstances, experience shows that by changing the nature of the substance injected, better results may be obtained.

PROPER EQUIPMENT FOR A RURAL PHYSICIAN.

By MELVILLE A. HAYS, M. D.,
New York.

Aside from the office furniture (including examining chair or table) which every physician requires, the equipment of a rural physician will depend entirely on whether he is going to rely on his own ability to practice medicine fully and conscientiously, or is going to depend largely on laboratories, specialists, and hospitals (near or remote) for a great deal of assistance; it will also be partly governed by the presence or absence of a reliable drug store where prescriptions may be properly compounded. In the absence of a drug store, the physician will be compelled to carry and dispense his own medicines. These can be secured, largely in tablet form to be dispensed as such or to be made into solutions, from one of the large drug supply houses. The variety of remedies carried and used will depend entirely on the average type of diseases to be treated, and the physician's own views on therapeutics.

If the physician is going to depend for assistance on laboratories, specialists, and hospitals, he will require, aside from necessary medicines, only the ordinary diagnostic instruments (including stethoscope, sphygmomanometer, etc.), a pocket case of

surgical instruments, and a full supply of surgical dressings—gauze, absorbent cotton, bandages, splints, antiseptics, ointments and dusting powders; his serious or puzzling cases will be sent to a specialist or a hospital, and his income will be reduced.

The up to date physician will do most of his own work, and will only refer exceptional or very serious cases to specialists or hospitals. His equipment will necessarily include the following:

Diagnostic.—Stethoscope; standard sphygmomanometer; headlight (electric battery), or mirror, with necessary specula, for examining nose, throat, ears, vagina, and rectum; microscope with necessary slides, cover glasses, and stains; uranalysis outfit with a suitable centrifuge; outfit for Widal reaction and outfit for examining gastric contents; suitable aspirating syringe and needles; materials for special tests for tuberculosis; and other aids as the occasion arises.

Medical.—If there is a reliable drug store near by, the medical equipment will include only hypodermic syringe and needles, with necessary tablets for emergency and other use; in the absence of such drug store, the physician will necessarily be compelled to carry and dispense a full line of therapeutic agencies.

Obstetrical and gynecological.—This will include suitable obstetrical forceps; ether and chloroform; pituitrin in ampoules; ergot; needles, sutures, and ligatures; disinfectant for hands; dilating bag for use in placenta prævia; compact gynecological operating set; vaginal specula; special remedies for local use; and gauze packing strips.

Surgical.—This will include a small portable and compact operating set for general use (similar to the one furnished by the U. S. Army); pocket case for emergencies; needles, sutures, and ligatures; gauze (plain and medicated); bandages (gauze, cotton, and plaster of Paris) and absorbent cotton; splints; antiseptics; special instruments for nose and throat work (tonsillotomes, adenoid currettes, etc.); anesthetics (local and general) and appliances for administering or using them; special hypodermic syringe and needles for administration of mercury preparations in the treatment of syphilis; irrigating appliances for treatment of gonorrhoea; apparatus for administration of salvarsan; apparatus for transfusions; and an aspirating set for general use.

Special.—Spray apparatus (either hand atomizers or compressed air tank) is necessary for the treatment of nose and throat affections. A small optical trial set is another essential which will add to the efficiency and income of the physician; its use may be easily learned. If there is an available supply of electric current, there can be secured and used a cabinet which is supplied with the appliances for diagnostic and therapeutic work, including an x ray outfit. Special work should be sent to a reliable laboratory.

The entire equipment as enumerated will not necessarily be required immediately upon beginning practice, but the essentials should be secured, and the other items added as the occasion arises. Some means of quick transportation, either horse or automobile, is absolutely necessary in all rural practice.

LONDON LETTER.

(From our own correspondent)

The Meeting of the British Medical Association at Cambridge.

LONDON, July 5, 1920.

The last time the British Medical Association met was in the far northern University town of Aberdeen in the fateful year of 1914, shortly before the outbreak of the world war, immediately after the Congress of Surgeons of North America was held in London under the presidency of Dr. J. B. Murphy, of Chicago. I attended that meeting and how well I recall that the air seemed charged with electricity.

The meeting of 1920 took place under very different conditions. In fact, no meeting of this association has been held under more favorable auspices than the eighty-eighth annual meeting. Everything seemed to conspire to render this gathering a conspicuous success. The long interval since the last annual meeting, the ideal place of meeting, Cambridge with its colleges and halls and lecture rooms, only fifty miles from London and a railway centre, and last but not least, the choice as president of Sir Clifford Allbutt, the grand old man of medicine, whose medical scientific knowledge is only equalled by his personal magnetism, his charm of manner, and his gift of oratory. The attendance was large and while fully representative of the British medical profession included also distinguished men from other countries. Dr. Simon Flexner and Dr. Alfred Hess represented research and clinical medicine in New York. Dr. Charles H. Mayo, of Rochester, Minn., and Dr. J. M. T. Finney, of Baltimore, surgery in the United States, and Dr. Brown and others from Johns Hopkins Medical School.

The comfort and entertainment of the visitors were well looked after and there was so much of interest to see in Cambridge that one did not quite know what to see and what not to see. Tours through the colleges were arranged and although Oxford is generally pointed to as offering more in the way of architectural, historical and archeological delectation, yet Cambridge, even if second in this respect, is, at least, a very good second. Indeed Oxford has nothing to show to compare with the wonderful King's College chapel at Cambridge and the quadrangles and hall of Trinity College are certainly not surpassed by those of any Oxford College. Garden parties were held at Downing College, Newton Hall, the Bishop's Palace, Ely, Christ's College, Croxton Park, and Madingley Hall and organ recitals were given by college organists at King's College chapel. Numerous excursions were also available, including one to the Cambridgeshire tuberculosis colony, Papworth Hall, situated about twelve miles from Cambridge. The museums with which Cambridge abounds were, of course, all thrown open.

A congregation for the conferring of honorary degrees was held in the Senate House on June 29th when the degree of LL.D., was conferred upon six distinguished medical men of two con-

tinents. The degree was first conferred upon Sir Clifford Allbutt, K.C.B., M.D., Fellow of Gonville and Cains College, regius professor of physic at Cambridge University. In his oration which, as is always the case, was delivered in Latin, Rev. C. E. Raven, dean of Emmanuel College, referred to Sir Clifford, as one whose wide study, admirable writing, and inspiring zeal had lifted him to a position in which both the medical faculty and the university looked jointly upon him as their own. It may be mentioned that Sir Clifford Allbutt is in his eighty-fourth year. The other recipients of the degree were: M. Jules Bordet, president of the Faculty of Medicine and director of the Institute Pasteur at Brussels; Simon Flexner, director of the laboratories of the Rockefeller Institute for Medical Research, New York; Dr. Piero Giacosa, a professor of materia medica and experimental pharmacology at the University of Turin; Sir George Henry Makins, G.C.M.G., C.B., president of the Royal College of Surgeons, and Sir Norman Moore, Bart., M.D., Honorary Fellow of St. Catherine's College, Cambridge, and president of the Royal College of Physicians. Four gentlemen were unable to attend to receive their degrees, viz., Mr. Albert Calmette, subdirector of the Institute Pasteur of Paris; Dr. Harvey Cushing, professor of surgery at Harvard University, Major General William Crawford Gorgas, and Sir Patrick Manson.

On the evening of June 28th, Sir Clifford Allbutt delivered his address as president of the association. The gold medal of the association was presented to the Bishop of Liverpool, as the father of the late Captain Noel Godfrey Chavasse, V.C., M.C., R.A.M.C., to whom the Victoria Cross was awarded in 1916, for extraordinary acts of bravery.

The Stewart Prize was presented to Miss Harriette Chick, D. Sc., in recognition of her own work and that of the band of scientific women associated with her in the investigations into the means for preventing scurvy and beri beri in armies and among populations suffering privations. The Middlemore Prize was presented to Harry Moss Pragnair, M.D., F.R.C.P., D.P.H., for his essay on perimetry, inclusive of scotometry, its methods, and its value to the ophthalmic surgeon.

After the presidential address the visitors, numbering about one thousand, were received on the grounds of King's College by the Master, Dr. Grove, and members of the Cambridge Huntingdon Branch of the British Medical Association. At 10 p.m. the company assembled in the hall of King's College, where Sir Clifford Allbutt was presented with a large portrait painted by Sir William Orpen. Sir Norman Moore made the presentation in a fitting speech.

The evidence afforded of the trend of medicine of the present day, was the most significant feature of the meeting. Judging from the prominence given to preventive medicine there would seem to be little doubt of what the future of medical practice would be. All the meetings concerned with preventive medicine were largely attended and it

was somewhat curious and in a way disheartening to note that the attitude of the medical men present appeared to be defensive. The medical profession seemed to fear state control. Sir George Newman, in his opening speech in the section in sociology, fully recognized this and endeavored to reassure the profession. While the chief medical adviser to the Ministry of Health undoubtedly meant what he said, he was quite unable to control or perhaps even greatly to influence the situation. As he said, he was after all only a servant, and it was to be feared that politics would rule the situation. It is obvious that the medical profession is impotent politically, while the Labor Party is powerful. Therefore, it is logical to argue that if the Labor Party desires state control of the medical profession they are not unlikely to get it. It is useless to evade probabilities because they are unpleasant and it was of sinister import that the labor representative who spoke at the meeting was wholly in favor of state control.

Another much discussed subject and one that is involved in the question of state control was that of the voluntary hospitals and what is to become of them. The medical profession here as a whole are unalterably opposed to the hospitals passing into the hands of a bureaucracy. Why is it necessary to rely upon the state for the maintenance of hospitals when an obvious way out of the difficulty is ready at hand? Why not introduce a pay system or a modified pay system? It is fair, and should provide sufficient funds to support the hospitals, partially at least. The state or municipalities might aid but there seemed to be no valid reason for the state having complete control. At any rate, the state should pay for insurance patients which, since the passing of the Insurance Act, had placed a great strain upon the resources of hospitals. If everyone paid for hospital treatment according to his or her means it would go a long way toward solving the problem. In the words of Sir Wilmot Herringham, who in discussing the future of the medical profession, dealt with the question from the viewpoint of the consultant, "The only sound remedy, as far as I can see, is to extend to private patients the benefit and convenience of treatment at a hospital. Paying hospitals are one of the greatest needs of the time." Mr. E. W. Morris, who is house governor of the London Hospital, and one of the greatest authorities on the management of hospitals in the world, in the same discussion gave it as his opinion that, considering the enormously increased cost of running the voluntary hospitals, the time had come when patients should as a matter of duty contribute to the cost of their treatment. From all this it will be gathered that the medical profession in Great Britain is in a critical condition. It is at the parting of the ways and it is earnestly hoped that in attempting to avoid the Scylla of unorganized practice it will not be forced into the Charybdis of state control. Sir George Newman said that individualism was the genius of British medical practice and it would be nothing short of a national disaster if that were to be lost or allowed to be destroyed.

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL

INCORPORATING THE

Philadelphia Medical Journal and the Medical News

A Weekly Review of Medicine.

money sent by unregistered mail.

Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, SATURDAY, SEPTEMBER 11, 1920.

PHYSICIAN AUTHORS — DR. ORLANDO WILLIAMS WIGHT.

A many sided man was Dr. Orlando Williams Wight, author, physician, lecturer, theologian, educator, linguist and traveler—a man who had an interesting and varied career in many lines of endeavor and who was a success in all. Dr. Wight seems to have had some difficulty in making up his mind definitely as to just what course in which to shape his destiny. He began by being an instructor in Eastern academies and when he was only twenty-three years old he became president of the Auburn (N. Y.) Female Academy. Here was a field in which he seemed destined to make a name for himself, but it was not to his liking and so he gave it up and went to New York city, where he began doing free lance work for newspapers and magazines. This was in 1847. At about that period he thought of becoming a minister of the gospel, and so studied theology and was ordained as a Universalist minister, but his religious activities ended there. He never entered the pulpit, but went to Europe in 1853, where he spent several years, renewing his literary work upon his return.

As a physician Dr. Wight was of the late blooming type. He was well along in his middle thirties when he began the study of medicine at the Long Island College Hospital, and was turned forty when he received his degree. He found the practice of medicine more fascinating than any pursuit he had yet attempted and he maintained his connection with it throughout the rest of his life. His first

work as a practicing physician was done at Oconomowoc, Wis., and subsequently in Milwaukee. In 1874 he was appointed surgeon general of Wisconsin and four years later became chief health officer of Milwaukee, in which position he served two years. When the board of health of the city of Detroit was reorganized in 1882 he became the chief health officer there and served until his death six years later.

It would take a five foot shelf with a roomy addition to hold all the volumes of original works and translations that came from Dr. Wight's pen, not counting the volumes he edited and revised, for he was an indefatigable worker. We hear little of him today because he chose literary paths that do not lead to heights of fame. His work was largely translating and he made of it a fine art. But translation is a difficult art and a thankless one, filled with empty honors. To Dr. Wight translation came naturally, for he had a gift for languages. He spoke French, German, Spanish and Italian fluently, and there was none in his time better versed in Latin and Greek than he. He had received a classical education at Westfield Academy and at the Rochester Collegiate Institute and before he had reached his majority was teaching Latin and Greek at Genoa Academy and mathematics and modern languages in Aurora Academy. It was because of his remarkable proficiency as a linguist that Yale University in 1861 conferred on him the degree of A. M. and later the degree of LL. D.

The translations made by Dr. Wight are standard today. They have stood the test of time because they reproduce the spirit and style of their originals; because they were the labor of love of a gifted man who was thoroughly familiar with the manifold complexities of the languages from which and into which he translated. Six volumes of Balzac, Pascal's *Thoughts*, the *Lives and Letters of Abelard and Heloise*, Victor Cousin's *History of Modern Philosophy*, a history of France in several volumes, fourteen volumes of the *Standard French Classics*, the works of Montaigne—these were some of the works translated by Dr. Wight. He also edited and did most of the translating of the *Household Library* in eighteen volumes. This consisted of a series of portraits of the world's most famous historical spirits, the first volume being devoted to Joan of Arc, translated from Jules Michelet's brilliant history of France. Other volumes in the series translated by Dr. Wight included the lives of Peter the Great, Mahomet, Martin Luther, and Socrates.

Dr. Wight had a strong preference for biography and believed that the study of the lives of great men and women made more stimulating and wholesome reading for the American public than what he called "the bloodless personages of mere fiction."

"Life and history," he said, "are always stronger than the day dreams of fancy; they can satisfy the cravings of the imagination while they feed the heart and instruct the mind."

Dr. Wight's own life was written by his brother, Dr. Jarvis Sherman Wight, who was an authority on craniology and author of several medical works, including *Suggestions to Medical Witnesses*. He was for many years professor of surgery and dean of the faculty of Long Island College Hospital, and it was largely through his influence that Dr. Orlando Wight decided to adopt a medical career.

Dr. Wight's contributions to magazines and newspapers would fill half a dozen volumes. His best known medical work was his *Maxims on Public Health*, published in 1884. One of his most successful volumes was his *Lectures on The True, The Beautiful and the Good*. His last book, *A Winding Journey Around The World*, was published the year of his death.

Dr. Wight came of an old colonial family. He was born in Centerville, N. Y., on February 19, 1824, the son of Thomas and Caroline Van Buren Wight, and was a descendant of Thomas Wight who emigrated to the American colonies from the Isle of Wight in the year 1635. He died on October 19, 1888.

VITAMINES IN THE NUTRITION.

Not long ago, A. Lumière, of Lyons, demonstrated that the majority of phenomena which constitute what may be called physiological insolvency can be explained by inanition. It then remained to show what part the want of vitamines played in the inanition. This has been accomplished by Lumière, who recently demonstrated that pigeons fed on decorticated rice—a food deprived of vitamines—ceased to eat after a few days. If the birds were fed by gavage they regurgitated all food given. These phenomena are dependent upon the fact that the alimentary bolus thus constituted is incapable of passing through the pylorus and remains in the upper portion of the digestive tract, especially in the crop, then in the gizzard. When pigeons thus fed are opened it will be found that with a complete alimentation the grains are abundantly impregnated with the secretions, the bolus formed by polished rice being drier. This alimentary bolus is found in the shape of a compact mass in the gizzard, in which gravel is present and in nor-

mal conditions crushes the grains which are as hard as plaster.

In these circumstances, it is evident that digestion cannot be carried out. Quite independent of the mechanical action which causes the food to progress onward in the digestive tract, the aliments ingested should, in the first place, undergo a phase of elaboration, consisting of their dislocation, disaggregation, and hydrolysis in order to give rise to substances whose simplified molecules may be able later to form by synthesis the complex albuminoid matter and other organic combinations which make up the elements of animal tissues. Now, this first act of nutrition can only be assured by the ferments derived from the glands of external secretion whose secretion is completely absent when decorticated rice is used as food.

The consequence of these data—which have been corroborated by the very ingenious experiments of Lumière—is that in the case of decorticated rice the necessary substances for setting up the glandular secretion of the upper digestive tract are lacking and these substances are the very ones called vitamines. Now, if to a pigeon which, following gavage, has reached the phase of intolerance, some drops of oil be given or even a very minute quantity of extract of malt yeast, the glands of external secretion will commence their functions, the alimentary bolus will progress through the digestive tract, and a copious stool will demonstrate that the digestive act has been carried out thoroughly. This is unquestionably a discovery of the utmost import and singularly enlightens the problem of vitamines and physiological insolvency which, until now, has been most obscure.

THE CLINICAL FORMS AND DIAGNOSIS OF ARTHRITIC CELLULITIS.

The clinical forms of cellulitis are numerous and vary according to the region in which the connective tissue is involved. The principal modalities are above all met with in the neuralgic domain. In the upper limb an intercostal pseudoneuralgia will be complained of by the patient, with pain seated in the cutaneous ramuscles which supply the skin of the thoracic walls and extend to the shoulder, arm and lumbar region. That the patient is not suffering from intercostal neuralgia will be made evident by pinching the skin over a nerve filament. This will elicit sharp pain, while compressing the skin over a rib will cause characteristic pain. Next in frequency as a clinical form of cellulitis comes sciatica, in which Valleix's points can be brought into evidence, which are obtained not only by com-

pressing the nerve on the underlying bone but also by pinching the skin over a corresponding area

Beside these neuralgias the trigeminus is the seat of pain when cellulitis is present at the point of emergence of this nerve. The neuralgias of the arm, forearm, and shoulder are frequent and often mistaken for joint disturbances; rheumatoid pain in the neck or shoulders is encountered, especially in women who are insufficiently protected by their clothing. Lumbosacral localization of cellulitis gives rise to neuralgia simulating lumbago and may lead to the erroneous diagnosis of a muscular affection. Cellulitis in the abdominal wall near the right iliac fossa has been known to simulate appendicitis, not only in the female but in males as well. Cellulitis around the joints gives rise to periarthritides characterized by a thickening of the tissues which aid in the protection and support of the joint, as well as general soreness of the joint and muscles.

By its symptomatology, as well as by its etiology, gout, another manifestation of arthritism, shows bonds of relationship to cellulitis. The presclerous edema of the subcutaneous connective tissues may extend to the tissue of the same nature surrounding the veins and produce a periphlebitis, which accompanies and invariably follows phlebitis, but can exist without the latter. It produces a feeling of weight in the lower limbs and abdominal region with cold and warm sensations.

In abdominopelvic cellulitis neuralgias occur which are due to the onset of the process in the connective tissue, although by palpation little can be detected. When the cellulitis becomes more marked, however, a doughy feeling is imparted to the organs in the true pelvis which may lead to a diagnosis of tumor, and should the cellulitis be accompanied by fever a suppurating process may be suspected.

Among all these clinical forms the diagnosis is sometimes a matter of some difficulty at first. The diagnosis of cutaneous cellulitis is not hard to make; the symptoms may not all be present but are very distinct when they exist. As far as cellulitic tumefactions are concerned, the continual change in their size, or even in their localization, makes the diagnosis easy. In subcutaneous cellulitis the exciting of superficial pain will prevent diagnostic confusion, for example pseudoappendicitis or sciatica. The presence of several foci of cellulitis in various parts of the body will also aid in diagnosis. Thus should there be any hesitancy as to whether a tumor or neuralgia is due to cellulitis and another focus is found, for instance in the arm or shoulder, the real condition becomes clear.

THE MIND OF A SURGEON.

Professor J. L. Faure, the distinguished French surgeon, has written a brochure, *L'ame du Chirurgien*, showing the triumphs and difficulties of the surgeon's life. He says: "There is not a man in the world who receives more often than the surgeon the impress of powerful emotions, sometimes pleasant, often tragic and sorrowful, but of an infinite variety and of which perhaps only the diversity permits him to endure without faltering the incessant repetition. In the battles which he fights each day and of which the stake is a human life, he knows one by one the pangs of imminent danger and the satisfaction of difficulty overcome. Abruptly and without transition he passes from the tranquillity of mind resulting from an ordinary operation to the sudden disquietude which springs from some unforeseen accident. His soul is engrossed in these constant struggles and sudden shocks. There is not an act of his professional life which for the surgeon does not entail grave responsibilities. From each of his decisions, each of his thoughts, each of his acts, and sometimes even from his gestures may arise the most fortunate results or the most tragic consequences. It is a grave and serious function, that of the man who each instant holds life or death in his hand, and the rôle of the surgeon is often of singular grandeur."

News Items.

Personal.—Dr. Harry J. Moss, superintendent of the Hebrew Hospital, Baltimore, has been appointed superintendent of the Brownsville and East New York Hospital, Brooklyn.

New York City Acquires Milk Stations.—The Nathan Strauss milk stations and laboratory, established in 1892, were taken over by New York on September 1st. Dr. Royal S. Copeland, health commissioner, accepted the plant on behalf of the city.

Death of Professor Wundt.—Word has been received from Leipsic of the death there on August 31st of Professor Wilhelm Wundt, at the age of eighty-eight. Professor Wundt held the chair of philosophy at Leipsic, where he had founded an institute for experimental psychology.

Southwestern Medical Meeting.—The fifteenth annual meeting of the Medical Association of the Southwest, composed of the States of Missouri, Kansas, Oklahoma, Arkansas and Texas, will be held November 22nd to 24th at Wichita, Kan., under the presidency of Dr. E. E. Day, of Arkansas City, Kan.

New Plan for Poliomyelitis Patients.—The 500 or more children suffering from poliomyelitis who have been receiving treatment three times a week in the clinics of city hospitals in charge of the Department of Public Welfare are to be put under a new plan of treatment. They are to be admitted to resident patients, and a public school teacher will be provided for each hospital. Many of the children have been unable to attend school, and the plan to be followed will prevent neglect of their education.

Red Cross Public Health Chair.—A chair of public health in the University of British Columbia will be endowed by the Provincial Red Cross of Canada, the Red Cross paying the salary of the professor for three years.

Abandoned Base Hospital Burned.—Twenty buildings of the former United States Base Hospital No. 1, now abandoned, in the Bronx, New York City, were destroyed by fire on the night of September 2nd. The damage is estimated at \$20,000.

Cholera in Corea.—A press dispatch from Corea states that there are 9,000 cases of cholera in Corea and that 3,000 deaths are reported there. Corean superstition has added to the difficulties in fighting the epidemic, as the natives conceal the bodies of victims in their homes to prevent cremation.

Increased Birth Rate.—The birth rate for the first seven months of this year is 22.34, as compared with a rate of 21.90 for the corresponding period in 1919, according to statistics of the New York City health department. In addition to this the infant mortality rate for the periods referred to has declined from 92 in 1919 to 83 for the present year.

Army Commissions.—Commissions in the Medical Corps of the regular army have been issued recently. Dr. Attilo M. Caccini, who for the last eighteen months has been engaged in sanitary work at the U. S. aviation camp at Garden City, L. I., was commissioned a major. Dr. William Frank McLaughlin, of Fox Hills General Hospital, Staten Island, received the commission of captain.

Tuberculosis Workshop.—A workshop and training school for the industrial rehabilitation of exservice men, convalescent from tuberculosis in the arrested stage, is being maintained in Long Island City by the Federal Vocational Board, the National Tuberculosis Association, and the New York Tuberculosis Association. As soon as the shop has become self-sustaining others than exservice men will be received.

The shop is incorporated under the name of the Reco Manufacturing Company, Inc., and is located at 458 Pierce avenue, Long Island City, in a large, airy, well lighted loft with lunch room and other conveniences. Medical care and treatment are at hand in any emergency. The object is to teach gradually and safely a trade that will not be injurious and in which, after the men have learned to make marketable goods, they will be paid the same wages as others doing the same work. An opportunity is thus offered to learn one of the following skilled trades under instruction of experts: Watch repairing, jewelry manufacturing (gold and platinum), or high class cabinet making. As soon as a man learns to make goods that can be sold or repairs that are paid for, he will receive the regular union wage for that particular kind of work. This training does not in itself affect any compensation he may now be receiving from the Government. To apply for admission, men must come in person to the New York Tuberculosis Association, 10 East Thirty-ninth street, New York City (third floor).

Memorial at Jefferson Medical College.—A bronze tablet engraved with the names of twenty-five graduates of Jefferson Medical College, Philadelphia, who lost their lives in the war, will be dedicated on October 7th. The tablet is the gift of the Alumni Association.

New York State Health Conference.—The nineteenth annual conference of sanitary officers and the second annual conference of public health nurses of the state of New York were held September 7th to 9th at Saratoga Springs, N. Y., under the auspices of the State Department of Health.

Railway Surgeons Meet.—The thirtieth annual session of the New York and New England Association of Railway Surgeons will be held Tuesday, October 19th, at the Hotel McAlpin, New York, under the presidency of Dr. William B. Coley, of New York. Among those who will deliver addresses are Dr. Joseph A. Blake, of New York; Dr. George W. Crile, of Cleveland, and Dr. Fred H. Albee, of New York. Clinics will be held at local hospitals on Wednesday and Thursday, October 20th and 21st.

Viennese Physicians in Need of Aid.—An appeal has been received from the American Relief Committee for Sufferers in Austria, of which Frederic Courtland Penfield, late American ambassador to Austria-Hungary, is honorary chairman, for the relief of destitute Viennese physicians and surgeons. The committee has created a special fund to aid medical men, who must combat an increasing mortality on pitifully inadequate incomes. Contributions may be made to Alvin W. Krech, president, Equitable Trust Company, 37 Wall street, New York, treasurer of the committee.

Died.

BEUKERS.—In Berkeley, Cal., on Monday, August 16th, Dr. Joseph M. Beukers, aged sixty-five years.

BOOKER.—In Selma, Cal., on Saturday, August 21st, Dr. Thomas Alvin Booker, aged forty-eight years.

BRADNER.—In New York, on Tuesday, August 31st, Dr. Frederick Clark Bradner, aged forty-seven years.

CALDERON.—In San Francisco, Cal., on Wednesday, August 25th, Dr. Eustorjio Calderon, aged fifty-nine years.

FOLLETT.—In Machias, N. Y., on Sunday, August 29th, Dr. William Follett, aged forty-nine years.

HAYES.—In Lock Haven, Pa., on Wednesday, August 25th, Dr. Joseph Henry Hayes, aged seventy-nine years.

LOWRIGHT.—In Allentown Pa., on Saturday, July 24th, Dr. James Harvey Lowright, of Center Valley, aged sixty-two years.

NILES.—In Marshall, Mich., Dr. William Holyoke Niles, aged thirty-five years.

PHELAN.—In San Jose, Cal., on Monday, August 9th, Dr. Daniel J. Phelan, of New York.

SHIMER.—In Easton, Pa., on Monday, August 23rd, Dr. Sterling Shimer, aged fifty years.

STUCKMEYER.—In Indianapolis, Ind., on Sunday, August 22nd, Dr. William E. Stuckmeyer, aged thirty-eight years.

TERRY.—In Providence, R. I., on Tuesday, August 24th, Dr. Herbert Terry, aged sixty-six years.

YODER.—In Catasauqua, Pa., on Tuesday, August 24th, Dr. Daniel Yoder, aged eighty-seven years.

Book Reviews

PSYCHOANALYSIS.

An Outline of Psychoanalysis. By BARBARA LOW, B. A., Member of the British Psychoanalytical Society, Formerly Training College Lecturer. Introduction by ERNEST JONES, M. D., M. R. C. P. (London), President of the British Psychoanalytical Society, etc. New York: Harcourt, Brace and Howe, 1920. Pp. v-199.

From a critical point of view it would not be difficult to find minor faults in this exposition of psychoanalysis, but in spite of the annoyance of frequent italics and more frequent capitalization, which are, no doubt, intended to emphasize more important words and passages, the book is well worth reading. Its purpose is to present to the reader a résumé of a comparatively new science—a science more far-reaching in its scope than any which man has heretofore attempted to study, and the work is given in a spirit of profound sincerity. Many new discoveries have been made. The entire old line psychology has been relegated to limbo, though they still teach the old psychology in schools and colleges. Many old pedagogues, fearful of being disturbed, do not venture into new fields. The unconscious mind is a vast newly discovered territory for which psychoanalysis presents a method of exploring. No more and no less. New valuations are frequently evolved from facing the conditions discovered. In a none too startling fashion Barbara Low has presented this fairly.

With the science in its early growth it is a bit early to set down concretely all its salient points. There is so much to say, so many new words to explain, and it is necessary to understand them all. Many surprising discoveries have been unearthed by the application of analysis. These are so diverse from what we have been in the habit of regarding as the behavior of the human mental mechanism that we are prone at first glance to reject them as absurd. The underlying motives of many of our everyday actions are explained and so frequently are our protective coverings torn away that we instinctively seek for shelter, resulting in the development of resistances. The very mainsprings of existence are tapped, matters of sex are brought to light, and an explanation is given for the repressions which surround us at every turn.

Barbara Low tells us that Freud in making use of various clinical material discovered the workings of the unconscious. He showed how certain emotional contents were rejected by the conscious mind and suppressed into the unconscious, which were then only revealed to the conscious mind in an acceptable form. One of the most common forms of disguising the unresolved complexes which had accumulated in the unconscious was by the use of the symbol. During sleep when the censor was relaxed these suppressed wishes were woven into dreams in which the symbol and other protective mechanisms were employed. Sex was one of the earliest things pushed back into the unconscious and therefore one of the most commonly disguised by the symbol. Sex also played the most prominent part in the unraveling of the unconscious, for there was so little place allowed for it

in the conscious existence in an undisguised form.

Much credit is given Dr. Ernest Jones for the work he has done in analysis in England. If it is made to appear that he has discovered some of the points to which reference is made in connection with his work, we must take into consideration the enthusiasm of the worker who has found so much inspiration in working with him. After all it matters little to whom credit is given. The source is not of primary importance. The vital thing is to understand the great forces which are constantly at work within ourselves and to apply the knowledge gained. To get full benefit from analysis, as Barbara Low points out, it does not suffice to get a cursory intellectual grasp of the underlying principles; it is necessary to plumb to the depths and reach the ultimate emotional level. Then we shall get down to true values.

She also shows how analysis can be applied to numberless fields of human endeavor; to the understanding of self, to the understanding of the urges which drive us on. She shows how far-reaching it can be made when applied socially, in teaching, and in an understanding of the new interpretation of the things that are studied. She shows how important a place in the social group the teacher has, how he may by his rigorous behavior in the class room create a twisted father complex or how by punishment create a sex sadistic complex. These are only a few points that have been brought out in this small book and many of the more vital ones in analysis have hardly been touched. On the whole, considering the condensation that was required, a great deal of territory has been covered and an understanding portrayal of the elements of psychoanalysis presented.

THE PROBLEM OF TUBERCULOSIS.

Tuberculosis and Public Health. By H. HYSLOP THOMSON, M. D., D. P. H.; County Medical Officer of Health, County Tuberculosis Officer, and School Medical Officer for Hertfordshire; Formerly Tuberculosis Officer for Newport and East Monmouthshire, etc. New York and London: Longmans, Green & Co., 1920. Pp. xi-104.

With laboring breath and halting steps, the thousands of tuberculous in England had faced the road which leads to cure, and the great wave of health they met was encouraging others to set out. The death rate was diminishing when war and progress met. In 1914 the number of deaths had gone down from 53,120 to 50,298; in 1918 it had risen to 58,073. The war emphasized the relationship between a deficient food supply and tuberculosis and showed that a diet rich in fats and vitamins is essential to protect the human body. Today the fight is renewed, heavily handicapped by the scarcity of food and housing, though often it is the nonhygienic habits of the householders which do the mischief. The mid-Victorian ideas of the viciousness of fresh air, especially at night, still prevail. Moreover, the construction of cities from a health point of view has never been considered, still less has any attention been paid to the question of housing for the tuberculous. But nothing will

be done effectually without the intelligent cooperation of the people. There must be amplification of the present system of notification; fats and sugars must be sold at reasonable prices; there must be abolition of insanitary areas, segregation of advanced cases, and the provision of a clean milk supply. All these seem simple weapons to fight so powerful an enemy, but none more effectual have yet been discovered. The modern tendency to provide hospital, sanatorium, and colony in one has proved the best. A large and suitable site and much expenditure are necessary, but the preventive treatment of advanced cases, the conservative treatment of quiescent ones, and the improvement of the economic standard of the patient are now maintained. As the type of common adult pulmonary consumption is rarely met with in children under fifteen, the usual form being latent tuberculosis of bovine origin, a special block or place should be provided for these.

Considered economically, tuberculosis is a great cause of poverty, and to complete the vicious circle, poverty is a great cause of tuberculosis, therefore all schemes for relief should have governmental and official support. The disease is a cause of death when life should be at its strongest, and the annual loss is estimated at many million pounds.

Even after apparent return to normal working health, the questions come swarming as to how that health shall be kept. Various other points are considered and ably treated by one who has wrestled with the problems in many responsible positions.

THE COLLOIDS.

The Use of Colloids in Health and Disease. By ALFRED B. SEARLE. With Foreword by Sir MALCOLM MORRIS, E. C. V. O. Illustrated. London: Constable & Co., Ltd., 1920; New York: E. P. Dutton & Company. Pp. vii-120.

Thomas Graham in 1861 added another perplexity to the medical sciences. His discovery that certain solutions would pass through a membrane and others not, threw light upon a state of matter of which little or nothing was known at the time, though so much in life and the commercial world depended on it. He gave the name colloidal (Kollagel) to that state in which substances may show characteristics in solution quite different from those of a true solution. These solutions he named sols. There are no groups of substances invariably colloid. Soaps dissolving in alcohol are correctly termed crystalloids. In water they behave equally characteristically as colloids. There are organic substances between the two which are called semicolloids. Each true colloidal particle carries a definite charge of electricity, some being electro-positive, other electronegative.

The difficulties of research seem endless, but the part to be played by colloidal sols and gels in hygiene is realized. Chadwick firmly believed that the entire removal of all conditions of dirt, including foul air and bad drainage, was an effectual preventive of all forms of epidemic, and here Mr. Searle goes aside to describe the peculiar behavior of soap, due to its colloidal character. He also frankly points out where the colloids hitherto have failed as germicides and disinfectants, but gives the hopeful views born of recent studies. The chapters on the uses

of colloidal remedies, with authentic cases of cure given by men like Sir James Cantlie and Sir Malcolm Morris, who found that colloidal silver had a distinctly soothing effect while curing perineal eczema, hemorrhoids, and enlarged prostate with irritation of the bladder, also contain much about colloidal mercury, iron, antimony, and manganese.

In conclusion it is urged that the colloids used by physicians should be prepared with the greatest care, for preparations good enough for the chemical lectures are usually too unstable for medical purposes. Also a small number of recent writers have confused colloidal elements and complex organic compounds which may be used either in a colloidal state or as a true solution. The condemnatory statements have usually been made by those with an imperfect knowledge of colloids, or relate to those nonisotonic with serum and other body fluids.

The author is surely justified in his plea that the discovery of artificially prepared colloids which are stable when in the human organism is so recent, yet the results after administration so interesting that they merit a clear setting forth, for the learned to become more learned and the unconverted more confounded and unable to answer.

WOMAN.

Woman. By MAGDELEINE MARX. Introduction by HENRI BARBUSSE. Translated by ADELE SZOLD SELTZER. New York: Thomas Seltzer, 1920. Pp. vii-228.

It is not possible to subscribe unqualifiedly to the extravagant praise which the introduction bestows upon this book. It is true that it has various poetic qualities which give the author a certain literary rank. It has truth, the fearless expression of the new attitudes, the untrammelled convictions of a young soul who must find life for herself. She must do more than this; she must live that life apart from the conventional molds to which it may attach itself even by its own choice. So in accepting the various experiences of womanhood, independence of parents, earning of livelihood, marriage, motherhood, even a second love, she strives for an independence which is the finding and the assertion of the need to live out her own inner self. There are other poetic marks, charm of style, the grace of enticing the moods of wind and weather to express the play and the cry of human feeling.

Yet when these things are appreciated there is a bitter flavor underneath, a slightly sour morbidity, one might say, which demands deeper probing. The woman, fictitious character though she may be, spends too much force upon self inspection. She might say she escaped morbidity because of her appraisal of all this self in terms of living and of loving widely. Yet there is an insistent note of narcissism, too much reference of it all to herself and in terms of herself. Her love, toward her male objects, her child, the friend of her own sex, turns upon itself for measurement and for definition, not toward the loss of itself in an extraneous outpouring. Superficially the book seems to reveal a high unselfishness which reaches out more truly than narrow conventions would allow. The rule of measurement, however, remains behind even in the beautiful body which fills the horizon rather

than forms only a stimulus to wider things. This is the reason why, when a new love intruded upon the old and took possession both of soul and body, it was counted justified. The more ancient experience of woman in giving herself to the free enjoyment of any claims upon her presented itself as this woman's right and her extravagant absorption in self obscured the reversionary character of this promiscuity. Her need to take as freely of love as of sun and air seemed to efface another need that belongs to progress, that of bending the rights of the individual to a restriction which has for its end a different broadening out beyond self.

The book does not speak entirely of such blind absorption in one's own need. It does represent the awakening of woman to greater sincerity with herself in her relation to life and love. It reveals the effort to obtain greater understanding and freer exercise of one's powers. It reveals, however, those inner psychic factors which emotionally forge chains about the self. For this reason the poetry is too self-indulgent and it becomes self-deceptive. It is true that the way out has to be learned first through a genuine valuation of soul and body which has been in danger of being forgotten, but one is tempted to remain only at this valuation. The franker literature of the present day, in which this more fearless evaluation of self is found, must nevertheless fix its eye upon a higher end. It must not begin and end with I and my.

THE SUPERSTITION OF CHESTERTON

The Superstition of Divorce. By G. K. CHESTERTON, Author of *Heretics*, *Orthodoxy*, etc. New York: John Lane Company, 1920. Pp. 11-150.

The controversy over the proposed changes in the divorce law in England has brought Mr. Chesterton rushing to the defense of the *status quo*. He comes, like the White Knight, equipped with all manner of fantastic and useless apparatus—puns, prejudices, paradoxes, anecdotes, epigrams, inconsistencies, and with a professed determination not to employ the "religious argument." Literally, he does not, but actually he speaks from the ecclesiastical viewpoint.

Mr. Chesterton does not believe in divorce because he does not believe in remarriage. Marriage, he says, is a vow, like poverty or chastity; it is "the idea of loyalty"; it is "a tryst with oneself." The tragedy of unsuited people he admits with a certain sadistic satisfaction; it is a "noble and fruitful tragedy, like that of a man who falls fighting for his country, or dies testifying to the truth." These arguments reveal Mr. Chesterton's mind—a mind occupied with the tenuous concepts of theological ethics and preferring noble attitudes to reality. For the whole conception of vows is a superstition, the superstition of an ancient theology which opposed the facts of human nature with an implacable idea. Man was ill at ease in the days of the church fathers, he was only in inconsiderable degree the master of his environment, and because he felt little and uncomfortable he bolstered up his courage with grandiose conceptions. Mr. Chesterton, of course, is only one of the many who still hold these conceptions, but in his case is found the *reductio ad absurdum*. No doubt he views the "tryst with oneself" and the gall-

ery of unsuited martyrs as an indication of the triumph of spirit over flesh. Perhaps, but too often that is a negation of joy and healthful love of living. And martyrdom is not a thing to be encouraged.

Mr. Chesterton was born some centuries too late. He should have been a fat, jolly friar of medieval times, penning polemics on the doctrine of original sin of debating how many angels could stand on the point of a needle. Such a contribution from him would be exceedingly interesting. But in the twentieth century he is ill at ease. Our "worthless, poisonous plutocratic modern society" does not please him and so he tilts at it like Don Quixote at the windmill—his weapon a paradox.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THREE YEARS OF WORK FOR HANDICAPPED MEN. A Report of the Activities of the Institute for Crippled and Disabled Men. By JOHN CULBERT FARIES, Ph.D. New York: 1920. Pp. 3-95.

ENOPHTHALMIC GOITRE AND ITS NONSURGICAL TREATMENT. By ISRAEL BRAM, M.D., Instructor in Clinical Medicine, Jefferson Medical College, Philadelphia, etc. St. Louis: C. V. Mosby Company, 1920. Pp. ix-438.

THE FUNDAMENTALS OF HUMAN ANATOMY. Including Its Borderland Districts. From the Viewpoint of a Practitioner. By MARSH FITZMAN, A. B., M. D., Professor of Anatomy in the Dental Department of Washington University, St. Louis. Illustrated. St. Louis: C. V. Mosby Company, 1920. Pp. iii-356.

THE INDUSTRIAL CLINIC. A Handbook Dealing with Health in Work. By Several Writers. Edited by EDGAR L. COLLIS, M. D. (Oxon.), M. R. C. P., Talbot Professor of Preventive Medicine in the University of Wales; Late Director of Welfare and Health, Ministry of Munitions, and H. M. Medical Inspector of Factories. Modern Clinic Manuals. New York: William Wood & Co., 1920. Pp. xii-239.

DIAGNOSTIC METHODS. Chemical, Bacteriological, and Microscopical. A Textbook for Students and Practitioners. By RALPH W. WEBSTER, M. D., Ph. D., Assistant Professor of Pharmacological Therapeutics and Instructor in Medicine in Rush Medical College, University of Chicago; Director of Chicago Laboratory, etc. Sixth Edition, Revised and Enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. Pp. xxxix-844.

MENTAL DEFICIENCY. (Amentia.) By A. F. TREGGOLD, M. D., F. R. S. (Edin.), Fellow of the Royal Society of Medicine; Consulting Physician to the National Association for the Feeble Minded; Consulting Mental Specialist to the Willesden Education Authority; Vice-President, Central Association for the Mentally Defective, etc. Third Edition, Revised and Enlarged. Illustrated. New York: William Wood & Co., 1920. Pp. xx-531.

AN ATLAS OF THE PRIMARY AND CUTANEOUS LESIONS OF ACQUIRED SYPHILIS IN THE MALE. By CHARLES F. WHITE, O. B. E., M. C., Major, Royal Army Medical Corps; Lecturer on Venereal Disease and Officer in Charge, Rochester Row Military Hospital; and W. HERBERT BROWN, M. D., Physician for Diseases of the Skin, Victoria Infirmary, Glasgow; Late Captain, Royal Army Medical Corps (T. C.). With a Foreword by Lieutenant General SIR T. H. J. C. GOODWIN, K. C. B., C. M. G., D. S. P., K. H. P., Director General, Army Medical Service. New York: William Wood & Co., 1920. Pp. vii-32.

Miscellany from Home and Foreign Journals

Causes and Definition of Cancer.—Leo Loeb (*American Journal of the Medical Sciences*, June, 1920) discusses the following factors that may enter as causes of cancer: External stimulation of a mechanical or chemical nature; internal chemical stimulation, especially through the action of internal secretion; heredity, which includes various not yet well defined factors, some of them probably identical with other causes; embryonal character of tissue or disturbances of embryonal development, including parthenogenetic development of the ovum; in an indirect way age; contact between normal and cancerous tissue; a possible effect of microorganisms. Cancer is abnormality of growth. Primarily it is a disturbance in the equilibrium of the individual, not through toxins but through an increased proliferative activity of the cells which is usually associated with an increased motility. This increase is long continued and often permanent. It is in all probability in the large majority of cases due to changes in cell metabolism which are of such a character that they propagate themselves. In some cases the same effect may perhaps be produced through extraneous causes, such as microorganisms.

Malignancy in Diseases of the Gallbladder.—J. F. Erdmann (*American Journal of Obstetrics*, December, 1919), among 224 cases subjected to operation for cholecystitis, found the gallbladder malignant in fifteen, or 6.7 per cent. All these cases were in females. In the report of the New York City Board of Health for 1918, nearly ten per cent. of the 2,170 deaths from cancer were instances of cancer of the liver or gallbladder. The frequency of cancer of the biliary system shows the following order: Gallbladder, cystic duct, and liver; pancreas, with common duct contiguity; common hepatic ducts; papilla of Vater. In all the author's victims of gallbladder carcinoma stones were found in the organ. Gallstones or biliary sand evidently act as a provocative factor in the production of malignancy. The statistical aspect of malignancy, as compared with the operative mortality, should be clearly placed before all patients with gallbladder disease. The mortality of cholecystostomy and cholecystectomy is well under four per cent.; in fact, below three and even two per cent. in the hands of experienced clinicians; and if it is recognized that the malignant incidence is between four and six per cent., the patient selecting the operative risk plainly has the advantage of avoiding a malignant death by two to three per cent. No definite symptoms of malignancy can be described in the early onset of the disease. When the gallbladder or mass in the right hypochondriac region becomes palpable in nonacute cases, with or without an ever deepening jaundice, malignancy must be given weighty consideration. Increasing jaundice, slow or insidious, is pathognomonic. Loss of weight is evident only when the tumor extends to the common duct, pancreas, or adjacent viscera. Many patients with gallbladder malignancy mention pain as the first

symptom. Removal of stones in these cases, without complete cholecystectomy, is prone to be followed by a rapidly fatal issue. A satisfactory cholecystectomy can be done in certain cases of involvement of the fundus and body of the gallbladder. These are the cases detected, as a rule incidentally to an operation for cholecystitis. Excision of sections of the common and hepatic ducts may be attempted but resection of the head of the pancreas is attended with undue risk. Involvement of the papilla and ampulla is best overcome by a cystogastrostomy.

Intussusception from Benign Tumor of the Intestines.—A. Murat Willis (*Surgery, Gynecology, and Obstetrics*, June, 1920) emphasizes the following points in intussusception resulting from benign tumor of the intestine:

1. The possibility, or indeed, the probability exists that benign tumors of the small intestine are of more frequent occurrence than the number of cases reported from surgical clinics would lead one to suspect.

2. There is no reason to believe that the material from the Boston institutions is unique and that Bostonians suffer from benign intestinal tumor more than persons in other localities. Accepting this, we face the striking fact that approximately one subject in every 1,500 coming to autopsy shows the presence of adenoma of the small intestine. Even more striking is the fact that in the 7,492 autopsies, benign tumors of the small intestine were encountered nineteen times, so that we have an incidence of nearly one to every 400 autopsies.

3. In considering the few cases of adenoma that have been reported by surgeons, it must be remembered that many of the so-called polyps are adenomatous in structure, but cannot be included because of the failure to make a histological examination of the tumor.

Acquired Immunity in Recent Grippe Epidemics.—Chauffard (*Bulletin de l'Académie de médecine*, April 27, 1920) refers to a theory recently advanced by P. Jacquet to the effect that whereas true epidemic influenza, such as that of 1918, confers actual immunity, the more common seasonal disorder generally labelled grippe is a nonimmunizing affection. Chauffard presents statistics on forty cases, comprising twenty-two men and eighteen women who developed grippe between October 13, 1919, and March 29, 1920. The eighteen cases in women were of a more or less severe thoracic type, ranging from diffuse bronchitis to instances of congestive or bronchopneumonic areas in the lungs. Of the twenty-two cases in men, fifteen were likewise instances of thoracic grippe, while seven were cases of milder, uncomplicated grippe. Out of the entire series of forty, eleven, or 27.5 per cent., had had an attack of influenza during the epidemic of 1918-1919. These eleven comprised eight men, or thirty-six per cent., with a history of influenza, and three women, or 16.6 per cent. Five of the eleven original attacks had

consisted of more or less severe thoracic grippe and six of mild, uncomplicated grippe. In no case, apparently, had the attack been one of typical febrile influenza with nervous manifestations. In view of the enormous number of persons afflicted in the great epidemic of 1918-1919 it seems remarkable that nearly three fourths of the more recent cases should have occurred in persons unaffected in the former epidemic. This ratio is of some significance as indirect proof of an immunizing action of epidemic influenza. The fact that none of the forty recent cases gave a history of nervous febrile influenza tends to show that, among the complex forms in which epidemic influenza occurs, the most specific and probably the most immunizing form is the nervous febrile variety which marks the beginning of great pandemics and runs its course without secondary infectious complications. Recognition of the immunizing property of influenza introduces the possibility of preventive vaccination against the disease.

Complement Fixation in Influenza.—H. J. B. Fry and C. Lundie (*Lancet*, February 14, 1920) carried out a rather small but carefully controlled series of experiments on complement fixation in influenza, using the sera of patients in a venereal hospital for investigation. The antigen used was prepared from an organism isolated from a blood culture made during the third wave of the epidemic. Control sera from normal individuals, syphilitics, patients with typhoid, malaria, and tuberculosis, and from patients with pyrexia of unknown origin were utilized. The results are summarized as follows:

1. The antigen shows greater or less fixation of complement with sera derived from cases of influenza, both recent and those occurring in previous waves of the epidemic.

2. This complement fixation is absent from the sera of normal individuals who have never had influenza.

3. It is absent in the case of sera from individuals who are suffering from other specific diseases and are free from any recent history of influenza.

4. An antigen prepared from a coliform organism, isolated as a contamination from the spinal fluid of an influenza patient, shows no fixation of complement with sera from cases of influenza.

Chest Measurements.—Robert M. Culler (*Military Surgeon*, June, 1920) writes of the futility of recording chest measurements at the nipple line, giving the following reasons for his deductions:

1. Lung capacity and competency cannot be estimated by a tape line nor actual lung disease excluded.

2. The degree of chest expansion or mobility, expressed in inches on reports of physical examinations, are of no value except to suggest developmental possibilities in the immature.

3. The form of the chest in young men is immaterial, since all forms can be increased in size by rib elevation through muscular development. None of the classical chest forms are incompatible with great lung power and physical vigor.

4. If chest mobility is to be recorded by inches, the measurements should be made at the level of the ensiform cartilage.

The Prevention of Respiratory Diseases in Infancy and Early Childhood.—John, Sobel (*Medical Record*, May 15, 1920) remarks that acute bronchitis and bronchopneumonia are the two diseases which cause most deaths in children under five years. In prophylactic measures two main considerations present themselves: 1, The need of placing the throat, nose, mouth and teeth in such condition, through nasal and oral hygiene, that the various bacteria ever present in these localities will find the throat and nose less favorable for either development; 2, that by the avoidance of overeating, overexercise, fatigue, irritability and a lack of the necessary amount of sleep, the general health may be kept at such a standard as to maintain sufficient resistance to ward off diseases of the respiratory tract or to minimize their effects.

Plea for Systemic Research Work in Endocrinology.—J. Aug. Hammar (*Endocrinology*, January-March, 1920) states that direct lesions of endocrine organs occur and frequently a certain clinical syndrome has more or less unanimously been considered to be connected with such lesions of one organ or another. To discern such direct lesions, at least when they are somewhat pronounced, our present knowledge has often proved sufficient. But in connection with exophthalmic goitre, Addison's disease, acromegaly and diabetes occur, formes frustes, in which the want of precision in our present anatomical knowledge is perceptible.

The endocrine organs are closely connected with each other functionally, so that a disturbance in the function of one of these organs involves a disturbance in the function of a larger or smaller number of the others. Whether this state of things is characteristic only of the endocrine system or whether after more careful research anything of this sort will also be proved for other organs of the body is another question. It is sufficient to establish that in such cases we must reckon not only with direct but also with indirect disturbances of the endocrine organs.

Mental and Nervous States and Military Efficiency.—Karl M. Bowman (*Military Surgeon*, June, 1920) discusses the relation of defective mental and nervous states to military efficiency, and states that there are in the United States a large number of cases of mental or nervous disease or defect. This is shown by the fact that, out of every twenty men rejected in the draft, one man was rejected for mental defect and one man for mental or nervous disease. During the war every army had large numbers of cases of mental or nervous disease which markedly impaired the efficiency of the fighting forces. To secure the most efficient army possible, it is necessary to eliminate the mentally unfit as soon as possible, but to use available cases of mental or nervous disease or defect whenever possible and where best fitted. To eliminate the mental defectives, the best way is to use the group examinations given by the psychologists to recruits. Such an estimate was perfected and used in our own army and is satisfactory. Borderline cases, depending on their mental age, their physique, and disposition, may be fitted for service. The majority of cases

with a history of a psychosis are unfit for military service. Those offering the best prognoses are: manic depressive, and infective, exhaustive psychoses; acute alcoholic conditions, *per se*, are not a bar to service; chronic alcoholic conditions, if pronounced or with paranoid tendencies. Especially should it be guarded against allowing arrested cases of dementia *præcox* and paranoia from entering the service. Every case must be judged on its individual merits and by a trained board of psychiatrists.

Of the psychoneuroses, all extreme cases are unfit for service. Psychasthenia and anxiety neuroses are the worst types; hysteria and neurasthenia are the best. Because of the high intelligence of many psychoneurotics, they are valuable individuals, and should be used, preferably in noncombatant service. The conscientious objector and the malingerer are frequently cases of mental disease, and, if so, should be treated as such; if not, they should be rigidly dealt with. To prevent nervous and mental diseases from occurring, the method used by our army in France is to be commended—and the method of treatment used is as good as has been devised. The public should be educated toward a truer understanding of the war neuroses in an endeavor to prevent their occurrence. In the future our army will be benefited in mental health and efficiency if the general education in the country is raised and English is universally known; if a program of general mental hygiene for the country is adopted; if syphilis is prevented and properly treated, and if a system of universal military service is adopted.

Sigma Test.—Herman Goodman (*American Journal of Syphilis*, July 1920) states that he has been attracted to the term sigma test or sigma reaction, which is coming into use in France and elsewhere as standing for the term complement fixation test for syphilis. The use of the Greek letter sigma Σ has had some popularity instead of the word syphilis, lues, or specific. For exactness in reporting the sigma test, the qualifying words Wassermann, Noguchi, alcoholic antigen, cholesterinized antigen, or others, may be added. As the doctor who receives and studies his serological reports becomes better acquainted with the technical side of the reaction, he insists that the laboratory inform him of the method in use. It certainly would be confusing if some test were reported Wassermann which was based upon principles and technic remote from the original.

The criticism that substituting the sigma for Wassermann would tend to accredit the test with specificity for syphilis can easily be disregarded, as those diseases which react positively and are not syphilitic in nature are infrequent, and those likely to meet with them can keep in mind that frambesia tropica (yaws), leprosy (nodular form), and possible sleeping sickness give the paradoxical positive. Another criticism that has more weight is that it adds another term to our nomenclature and that the older and now well known phrase Wassermann test will endure, even as the word salvarsan has been deeply rooted as standing for the chemotherapeutic arsenic compound which has been given the new American name arsphenamine.

Practical Considerations in the Diagnosis of Peripheral Nerve Injuries, with Special Reference to Compensatory Movements.—Samuel D. Ingham and John H. Arnett (*Journal of Neurology and Psychiatry*, February, 1920) state that in examining the results of a large number of peripheral nerve lesions, the characteristic and classic symptoms will commonly be found; however, a certain number of cases will exhibit unusual phenomena. These atypical cases are the ones that offer the greatest difficulties in neurosurgical diagnosis. It is inadequate simply to learn a list of the classic symptoms as signs of nerve injuries. The fundamental requisites for accurate diagnosis in such cases include a thorough anatomical knowledge, a mastery of the mechanics of joint action and discriminating observation. With the application of these broad principles to neurosurgical diagnosis, the difficulties are minimized and the proper treatment can be confidently instituted.

Toxicity of Phenylacetic Acid.—Carl P. Sherwin and K. Sellars Kennard (*Journal of Biological Chemistry*, December, 1919) find that phenylacetic acid, which is one of the most important putrefaction products of the normal human body, is not nearly as nontoxic as it was believed to be. Experiments on a hen, a dog, a monkey, and twelve adult males showed that where this acid was ingested thirst, nausea, and in the case of the humans, symptoms of poisoning, not unlike those of alcoholic poisoning, were produced. To determine the toxicity of the acid a dog was fed increasing doses until the seventh day, when death occurred. Microscopic examination of the kidney showed that the secreting epithelium of the proximal convoluted tubule was affected and the epithelium of the arched collecting tubule also showed evidence of a destructive action, while the secreting epithelium of the limbs of Henle's loop showed the most involvement. The interstitial tissue of the kidney, the straight collecting tubules, and the endothelium of the blood vessels did not appear to share in the destructive process.

Congenital Absence of the Vagina and Uterus.—W. R. Robinson (*Surgery, Gynecology and Obstetrics*, July, 1920) states that:

1. The diagnosis of absent vagina and uterus, or of vagina alone, can in most cases be made from the clinical history, supplanting at times the physical examination, when the latter is not readily obtainable.

2. Operative measures tending to create a vaginal tract should be undertaken only in individuals who are physically and psychologically women, in the full sense, which this definition implies.

3. In order that the newly constructed vagina should approach the normal as closely as possible it should be lined with a soft, lubricated mucosa, and the employment of an intestinal loop for that purpose, as advocated and executed by Baldwin, is the choice operation.

4. It is my personal belief that it is much safer to start the separation of the tissues interposed between the rectum and the bladder, in order to establish the copulating channel, from above, instead of from below.

Proceedings of National and Local Societies

BRITISH MEDICAL ASSOCIATION.

*Eighty-eighth Annual Meeting, Held June 25, 1920,
at Cambridge, England.*

The President, Sir CLIFFORD ALLBUTT, in the Chair.

President's Address.—The title of Sir CLIFFORD ALLBUTT's presidential address was *The Universities in Medical Research and Practice*. He said that the better class of general practitioner of fifty years ago was rather after the kind of Hippocrates or Paré than of the modern graduate. His university, in the days before great cities, was nature; in his clinical experience he enriched the instruction, half empirical, half dogmatic, of his medical school by the shrewd, observant, selfreliant, resourceful qualities of the naturalist. His science and practice were of the naturalist, not of the biologist. In Sir Clifford's early days a country drive with such a doctor in Yorkshire used to be one of the rewards of the consultant and a bedside talk with him a lesson in quickness of hand and wit, and of instructive inference and prognosis. He was as clever as the modern cardiologist in knowing when to give digitalis and when to withhold it, even if he were content to diagnose a case as "some bedevilment of the liver." His rules of thumb were not without their efficacy and his flair for the issues of disease marvelous. He did not come across much science, and what he did see of it, chiefly in casual *locums*, did not attract him much: for in truth half science was less useful to him than whole craftsmanship. He was a woodland guide, not a geographer; but as Aristotle and Darwin well knew, the woodlander gathers much curious lore.

However, in the march of intellect this comrade, kindly and loyal as he had been, was gone, and his sort of wisdom died with the individual. Who was to come next? The official doctor, or a family physician more intellectual but no less independent? An official doctor would be as alert and as progressive as a country parson whose service was not much kindled by the changes of promotion to an archdeaconry or a bishopric; while to shift an official doctor from place to place would be to cut the inner threads of those intimacies which we were now declaring to be the clews to the detection of diseases at their sources. Yet as things were, the independent practitioner was isolated; even in a town he was apt to make a little orbit for himself, to drift out of intimacy, perhaps into some jealousies with his brethren; he lacked mental incentive, and gradually let slip occasions of scientific reunion and renewal. Indeed he could not readily leave home to attend scientific meetings, so that too often, as Morsant complained, medical men did not think nor express themselves in a statesmanlike way. His time even at home was so broken up that he lost the habit of study. He might leave his hospital school full of ardor and in rapid growth, but in practice his ardor cooled and he dropped into routine; or at any rate such was his peril. And so less and less might the doctor feel himself a member of

a great profession; he might drift out of public affairs, his outlook and his sympathizers might diminish, his work become a trade, and his medical neighbor his opponent.

Again for some years past a few of us had been protesting against the clipping of family practice by official shears to see the subjects of infectious fevers carried into isolation, and the tuberculous and syphilitic disappearing with them. The children were turned over to the school doctor, the parturient women to the new midwife, and so on. What was to be the end of this pollarding of family practice? Were its branches to be scattered about in a wilderness of specialties and the family physician be a mere sweeper up of unconsidered trifles? Panel practice, for some time discredited by its hereditary taint of the club of infamous memory and by the continual dearth of the means of its development, should, if duly provided, expand into a large, honorable, and even universal department of medical work. The terms of engagement were to be more liberal, the clockwork was complete.

But how was the practitioner to rise to higher standards of modern science and skill when no means of investigating disease or making an intimate diagnosis were provided for him? He was well aware that modern methods of medicine depend on such means as x rays, a battery of stains and other cultural and biochemical apparatus; and not only an education in the use of these, but also the time to give to them. What should we think of a regiment of recruits called out to fight the enemy but unprovided with weapons or munitions? If the doctor was near a university, he could get blood tested for morphological elements or for sugar or nitrogen content, excretions analyzed, bacterial examinations and vaccines made, and so forth, but it was imperative that these opportunities, now confined to the few, should be universal. Moreover, if they were to be fruitful, the practitioner must consult personally with the scientist. These plants with their staff must be established in all districts, together with a much larger provision of cottage hospitals. In the United States medical men were banding together in districts for such a development of their private practices. Five or six of them combined to rent a house with consulting rooms for each, a common apartment for minor surgery, and so on. Each member of the alliance—they were not exactly partners—was expected, in addition to his general practice, to take up special work supplementary to the others so that a fair variety of special skill might be available in the house, skill which, if not of high expert value, was yet quite sufficient for ordinary diagnosis and treatment. For this purpose visits of members of special clinics and ordinary holidays were naturally arranged. Patients liked the system; they saw that it was more thorough. Domiciliary visits became fewer, yet there was always one of the group on the spot. The fees were received by a secretary attendant on the separate account of each member,

and after all upkeep expenses were met the surplus was divided according to the credit of each. The individual earnings were higher than on the separate practices. Such were some of the material advantages, the spiritual were the disappearance of petty jealousies in a spirit of comradeship and a larger freedom for scientific and social life and for public service. The patients learned that a due remuneration of medical service was no longer gained by a multiplication of visits nor by profits of dispensing. These ends could no doubt be attained by different methods, but the essential need was the generally accessible laboratory and staff, to be a little academy and place of reunion, possibly a centre for the meeting of the divisions of this association. But one word of caution; this centre must not be municipal, it must be free from all kinds of officialism and kept alive by a small committee of local practitioners in alliance with the Insurance Committee.

Surgical Treatment of Gastric Ulcer.—Sir BERKELEY MOYNIHAN said that the necessity for the surgical treatment of gastric ulcer was a confession that medical treatment had failed. As commonly employed it was doomed to failure. The surgical treatment of a chronic gastric ulcer called for the performance of one of the following operations: gastroenterostomy, excision, gastroenterostomy combined with excision by knife or cautery (Balfour's operation), gastroenterostomy combined with jejunostomy; resection of a part of the body of the stomach (sleeve resection), partial gastrectomy. Moynihan first reviewed and criticized gastroenterostomy and stated that in consequence of his experience he had abandoned gastroenterostomy alone in the treatment of chronic gastric ulcer, because: 1. The results, even when the operation was successful, were not so satisfactory as those which now followed gastrectomy. The morbidity was greater, the return to health slower, a more watchful aftercare was necessary. 2. Some patients returned with the ulcer still open, and a further operation was required. In such cases the ulcer had almost always perforated all the walls of the stomach, and adhesions had occurred to the liver, pancreas or abdominal wall. 3. Some few patients returned with carcinoma of the stomach after so long an interval as to make it probable that the cancerous change had occurred after the operation had been performed. Estimates of this sort were fallacious, for the chronicity of some forms of malignant disease of the stomach was remarkable. He had recently been consulted on account of a return of her symptoms by a patient upon whom four years and seven months ago he performed gastroenterostomy for carcinoma of the lesser curvature of the stomach, causing obstruction; secondary deposits were present in many glands, in the falciform ligament (one of these nodules was removed for microscopical examination and confirmed the diagnosis), and the liver. 4. There was evidence to show that gastric ulcer might develop even after gastroenterostomy had been performed, when the stomach itself was normal. Excision of the ulcer was given a fair trial but for various sound reasons had been abandoned by Moynihan.

Excision with gastroenterostomy had been found to be superior to gastroenterostomy alone. Concerning excision by cautery, Moynihan said Balfour, of Rochester, with that fertility of resource which was one of the characteristics of his fine work, replaced the method of excision of the ulcer by that of its complete destruction by the actual cautery. Balfour's operation had among its many merits that of simplicity. If an ulcer lay upon the lesser curvature or near it, a little nearer the cardia than the pylorus, or down upon the posterior wall, the operation of excision was likely to be difficult. The method of Balfour made the treatment much easier, quicker, and safer and gave far more satisfactory results. Gastroenterostomy combined with jejunostomy was a method which Moynihan had advocated and practised in cases of grave difficulty and the results had been excellent. There were ulcers of the stomach so large, so awkwardly placed and so deeply penetrating the liver or the pancreas, in patients whose general condition was poor, that any operation became serious. Such cases might be unsuitable for Balfour's operation by reason of the size or remoteness of the ulcer, and for the operation of gastrectomy by reason of the extremely feeble condition of the patient, who had perhaps recently suffered from a copious hemorrhage. In all such cases Moynihan performed gastroenterostomy in Y, generally by the anterior route. The operation of resection of a part of the body of the stomach—sleeve resection—was, of course, reserved for those cases in which the ulcer occupied approximately the middle part of the stomach. After resection of a cylindrical portion of the organ the cut ends were united. Advocacy of this operation appeared to be restricted to a few surgeons, and consequently the number of cases performed was relatively small. He practised it on two occasions only, long ago. In both the operation promised well, but one of the patients returned after four years with an hourglass stomach, for which a second operation was necessary. The rôle of the operation was necessarily very limited.

Moynihan contended that the diagnosis of gastric ulcer was often inaccurate and that a host of diseases, organic and functional alike, were called gastric ulcer. Consequently much literature and most of the statistics dealing with the subject of gastric ulcer lacked that foundation of truth which only an accurate diagnosis could afford. In the cases of indisputable gastric ulcer, when the ulcer was demonstrated beyond cavil by a radiological examination or by inspection upon the operation table, a far greater seriousness attached to the disease than to the condition of duodenal ulcer. Operations upon it were more serious, partly by reason of the extent of the operations themselves, but chiefly in consequence of the less robust state of the patients. This on reflection was not so startling as might at first appear, for many of the patients suffering from duodenal ulcer were otherwise of robust strength and splendid health. Moynihan had operated upon international football players, golfers, lacrosse players, and many distinguished athletes, for duodenal ulcer. Such people were not often found among those who suffered from gastric ulcer; though

there were exceptions, the types of stomach found in the two diseases were distinct from one another, as Hurst had shown.

Moynihan leaned to the belief that many of the cases of carcinoma of the stomach with which a surgeon could deal successfully had their origin in a chronic ulcer. That was not the universal view, but the opinion of those that hold it was weighty and well founded. Prompted by all these considerations, he was gradually brought to the view that gastric ulcer was a disease requiring direct and radical treatment and that it was not safe to trust to the direct method of gastroenterostomy, which whether its action was physiological or mechanical, merely produced a condition of things in which healing could more easily take place. As for partial gastrectomy, the operation of his choice, the risk was not great; over a period of ten years it has not been more than 2.5 per cent. All things considered and account being taken of the five years succeeding operation, it was probably a safer and certainly a more immediately satisfactory operation than gastroenterostomy alone. It could not always be practised. The ulcer might be so large and so placed as to make removal a matter of such great technical difficulty that the immediate hazards were unfair to the patient. But as experience grew the number of such cases diminished.

Moynihan said that nowadays he very rarely practised any other operation than partial gastrectomy or gastroenterostomy in Y combined with jejunostomy. He gave the technic of his partial gastrectomy operation for gastric ulcer, and statistics of results as follows: There were in all 835 operations since the year 1909, with twelve deaths, a total mortality of 1.43 per cent. Excluding the cases of jejunal ulcer there were 808 operations or cases of gastric and duodenal ulcers with ten deaths, a mortality of 1.23 per cent. This included all kind of operations; as stated before, his operative mortality with partial gastrectomy was 2.5 per cent.

Dr. CHARLES MAYO, of Rochester, Minn., discussed factors in the etiology, symptomatology, treatment, complications and results of gastric ulcer. He pointed out that gastric ulcer was more common in males than females and that according to statistics of the Rochester Clinic duodenal ulcer was four times more frequent than gastric ulcer. Medical treatment was chiefly dietetic, and duodenal ulcer rarely became malignant. Gastric ulcer was not caused by traumatism, neither was perforation as serious as believed. The best means of diagnosis was by the x ray; by this agency an accurate diagnosis could be made in ninety-five per cent. of cases, differentiating between gastric and duodenal ulcer. Cancer of the stomach rarely occurred with high acidity. Gastric ulcer was potentially malignant. Copious statistics were given and the various forms of operation practised at Rochester were described in detail. Both Moynihan and Mayo emphasized the wisdom of using absorbable sutures for this operation. Mayo, quoting from Hunter of the New York Life Assurance Company, stated that the operative mortality of gastric ulcer was three per cent. over normal while that of duodenal ulcer was less than normal.

Mr. HERBERT PATERSON, of London, referring to the question of whether gastrojejunostomy exerted a physiological action or was solely mechanical, said that as scepticism was the sure precursor of belief the scepticism displayed by some as to the physiological effects of gastrojejunostomy was a sign that they would soon be converted to his way of thinking. Mr. Paterson showed on the screen the physiological effects of this operation. These effects enabled Nature to relieve or cure hyperchlorhydria by her own methods, which were better by far than artificial means. He did not believe that malignancy was grafted upon chronic gastric ulcer, but was of the opinion that when a gastric ulcer developed malignancy, the ulcer was inherently malignant. He said that either malignant disease did not develop on gastric ulcer or gastrojejunostomy was a cure for cancer.

Mr. BURGESS, of Manchester, said the object was to get rid of gastric ulcer by abolishing the pathological basis, namely, the hyperacidity. The effect of the cautery was superficial, but hyperacidity was best cured by gastroenterostomy. However, gastroenterostomy alone was insufficient; the logical combination was excision and gastroenterostomy of which gastroenterostomy was the essential part. The physiological effect of gastroenterostomy had, in his opinion, been proved beyond doubt. He emphasized the importance of aftertreatment.

Mr. CHARLES RYALL said that gastric ulcer was a simple inflammatory process. He was in favor of gastroenterostomy from the physiological point of view. The kind of operation must be in accordance with the conditions found, but he did not believe in laying down the rule that partial gastrectomy must be done in all cases of gastric ulcer. The cautery was dangerous and too much importance was attached to the connection between chronic ulcer and cancer.

Dr. FINNEY said that he had been through the whole gamut of operations and failed in a sufficient number of cases to produce scepticism. Therefore he was never too sure and he thought it is unwise to lay down hard and fast rules for operation. All cases must be judged by the conditions found. Finney also disbelieved in any sure method of diagnosis. He had opened the abdomen and even the stomach and then he did not know whether there was an ulcer.

Mr. BILLINGTON said that Sir Berkeley Moynihan had taught much concerning the surgery of gastric ulcer. In his opinion the site of the ulcer should determine the kind of operation. The depth and penetration of the ulcer were also factors that must be considered. As a rule partial gastrectomy was not worth the risk. He inclined to gastroenterostomy.

Mr. ROWLANDS, of London, did not believe that the x ray could be depended upon for the purpose of diagnosis, and he put down the failures of gastroenterostomy to bad selection of cases and defective operative technic. Gastroenterostomy should not be entered into lightly. Gastroenterostomy exerted physiological effects. Partial gastrectomy was indicated in some cases but in the hands of the ordinary surgeon was a perilous undertaking.

Sir GEORGE MAKINS thought there was little doubt that malignant ulcer did follow simple ulcer of the stomach. Sir Berkeley Moynihan doubted whether any physiological results ensued upon gastroenterostomy. He thought the alleged physiological effects of the operation were nonexistent. Partial gastrectomy cured in the right cases.

Professional Secrecy.—Dr. LANGDON-DOWN, of Hampton Wick, moved that having considered the question of professional secrecy, more particularly with regard to venereal disease, the representative body reiterate the opinion that the medical practitioner should not in any circumstances disclose voluntarily without the patient's consent information which he had obtained from that patient in the exercise of his professional duties. Dr. Langdon-Down held strongly that the medical profession should not deviate from the position it had always taken in the matter, that secrecy should be maintained. There were cases, he said, in which one received from a court of law an order to divulge one's professional confidence. That was a recognized thing. There were also cases in which the professional man would defy the order of the court and take the consequences. If that was done in a sound case the punishment should not, and would not, be unduly severe. There were also cases when the medical man might feel it his duty to divulge a secret received in a professional way in order to prevent the committing of crime. The question was whether we should weaken our rule by satisfying these exceptions. If there was a breach of confidence between the doctor and the public, untold damage would result. We would do well to adhere to our old rule of secrecy, leaving the doctor, in those cases in which there was doubt, to decide whether there was a sufficiently compelling reason for him to break his confidence.

Dr. T. R. Bradshaw, of Liverpool, proposed that the question be referred back to the medical council. He said that they had clear ideas as to what secrecy meant, but it was a different matter to write those ideas down and formulate them. The council, he hoped, would find words upon which the profession could agree. Mr. E. H. SNELL, of Coventry said there certainly was a difference of opinion as to what a medical man should do in the case of syphilis. Some believed that nothing should be disclosed unless the patient consented, while others thought the man who declined to disclose ought to be shot.

Dr. CHRISTINE MORELL, of London, expressed herself as strongly opposed to referring back. She said that if we did not know what we wanted, we could hardly expect the public or state to support us. We were at the parting of the ways on this question. If we had no definite opinions we should be bound by the State and society to divulge practically all we knew about patients. Dr. Bishop Harman, of London, said the question of venereal disease made it necessary that there should be a rule and a clear view as to what medical men should do. The solicitor of the association stated the legal position. He said that so far as the legal profession was concerned, secrecy was not recognized by the law. So far as secrecy in the church was concerned, it was based on sentimental and not on

legal grounds. In America there was an enactment that no doctor should be compelled to disclose any information he might have received in his professional capacity, and in Scotland a court decision was recorded that secrecy was an essential part of the contract between the doctor and the patient. Secrecy had grown up by custom and strong common sense, as regarded solicitors. It appeared to him that they would be aiming at almost the impossible in endeavoring to get an Act of Parliament to establish that if a medical man knew that secrecy was going to cause crime he would be justified in telling. He submitted the following substitute for the resolution: That having further considered the question of professional secrecy from the viewpoint of the medical profession and with special regard to venereal diseases, the representative body reiterated the opinion that the medical practitioner should, not without his patient's consent voluntarily disclose information which he had obtained from such patient in the exercise of his professional duties.

Dr. C. SANDERS, of Stratford, asked whether the resolution meant that as a profession we were to allow a bounder to live and his wife and child to die. Dr. Langdon-Down pointed out that from the nature of the case we had a fluid, elastic and difficult set of circumstances which it was impossible to define in a brief resolution. We wanted to make our position such that in time of difficulty a man should be guided by judgment and common sense. Dr. BISHOP HARMON said that if a man was affected with venereal disease and the doctor held his peace, he would be affecting somebody else. In that case, if he could save persons from death or a life of misery and did not do so and that circumstance became known, would he not be liable to have an action brought against him by the person injured? If anybody took that course he would win hands down. They could not say that in no circumstances would they disclose information. He asked them not to be afraid of being illogical if there were instances which needed it. The resolution as drafted by the solicitor was carried with only two dissenters. Dr. SHEAHAN, of Portsmouth, moved that the medical profession be placed on the same footing, as to professional secrecy, as clergy, barristers, and solicitors. He remarked that the most advanced and civilized peoples in the world were the Americans and Scotch, and the latter, the most careful people in the British Isles, adhered to secrecy, it was only England of the present day that did not. Dr. Sheahan's motion was defeated. Dr. DAIN, of Birmingham, moved that the council be instructed to consider the extent to which and the ways in which the association was prepared to support its members in maintaining professional secrecy. The resolution was carried.

Report on Medical Services.—At the resumed meeting, June 29th, the main discussion was on the interim report on the future provision of medical and allied services, issued by the Medical Consultation Council of the Ministry of Health and containing proposals for the coordination of all medical services, infirmaries, hospitals, dispensaries and the like, thus insuring that the health resources of

the country should be fully exploited by the community without actually being taken over by the State. Dr. Turner moved that the representative body should express a general approval of the report and stated that such a drastic change in the handling of public health could not be forced down in a lump but would come by degrees. On this motion Dr. C. Buttar, of London, moved that the meeting define the general principles contained in the report and that these principles be submitted to the divisions for an expression of opinion. He contended that they were asked for premature approval. Sir James Barr, of Liverpool, made a slashing attack on the scheme. He said we ought to consider what the scheme was going to cost. His estimate was that if it was carried out as it should be the cost in the first five years would be one hundred million pounds a year and in the next ten years one hundred and fifty million a year. He had heard it said that this was an ideal scheme, but an ideal scheme must be practical. If a man wanted to change his residence to the moon he did not consider whether it was ideal or not, he turned it down because it was not practical. This whole business started with Sir Auckland Geddes, who had told Mr. Lloyd George that if he only had a proper scheme there would be no C3 men but all A1. Mr. Lloyd George was credulous enough to believe him. The result was that Mr. Lloyd George began to think how the population could be made A1 and he established the Ministry of Health, which had no more to do with health than the man in the moon. The Local Government Board had done remarkably well. No one could convert C3 men into A1 men by act of Parliament. In his view the State should be engaged not in the treatment but with the prevention of disease. Adenoids was a perfectly preventable disease, pneumonia was also preventable, and chronic disease of the heart was altogether preventable. Dr. Fothergill, of Brighton, warned the medical profession to be careful, as otherwise they would be jockeyed into a scheme as they had been jockeyed into the insurance business.

Lord DAWSON, chairman of the English Consultative Council and a member of the council of the British Medical Association, who is largely responsible for the drafting of the interim report, said the report only pretended to give the broad outlines of the direction in which the medical profession should move. It was time we asked ourselves whether we were going in for individualism or for something of the nature of State action. This scheme might take twenty years to materialize. The medical profession stood higher today than ever before in the estimation of the public, who looked to the profession for guidance as to the form medical practice should take in the future. Many points were raised by delegates, and ultimately it was resolved that the gathering should consider the general principles contained in the report and submit the whole question to the divisions, and that it be considered at a special representative meeting. The report recommended the establishment of primary health centres equipped for services of curative and preventive medicine, to be conducted by the general practitioners of the various districts in

conjunction with an efficient nursing service. A resolution was proposed affirming that the establishment of these centres was the pivotal idea of the changes recommended. Lord Dawson supported the motion. The idea, he said, was that the State would provide the equipment, but this would not alter the relations existing between doctor and patient. It was intended that the centres should be on a part time basis. There had also been favorably considered the attaching to the centres of provision for what might be called the intermediate section of the community as paying patients. A resolution was passed declaring that in order to attain the objects of an ideal system of medical and allied service, it was necessary that the prevention of disease as well as the provision for its treatment should be based on domiciliary medical service, and that general active practitioners should be actively encouraged in the practice of both. Reference was made to the wisdom which had been displayed in the setting up of the Medical Consultative Council to the Ministry of Health, and the conference carried a resolution regarding the council as an important step in an essential organized means whereby the medical profession could exercise its influence on the health policy of the nation.

Unqualified Medical Practitioners.—The question of unqualified medical practitioners was raised by Dr. R. HOPKINS, of Southwest Wales, who moved that steps should be taken in the public interest to bring to the notice of Parliament the injurious effects of unqualified practice in medicine and surgery. During a brief discussion of the subject it was stated that at present in Glasgow fifty unqualified persons were going about vaccinating people. The resolution was agreed to and a promise made that the committee of the association should bring the matter to the notice of the government.

Hospital Service.—Dr. BOLAM, chairman of the Hospitals Committee, submitted the following motion on behalf of the council of the British Medical Association: That for all work for soldiers and sailors, whether discharged or not, for any disease or injuries connected with the war, the medical staff of voluntary hospitals should be adequately remunerated. For the present the remuneration should represent an addition of not less than twenty-five per cent. to the cost of maintenance for inpatients, and not less than twenty-five per cent. of the ascertained cost for outpatients, the additional sum to be placed at the disposal of the medical staff; that in the case of special clinics, the fee payable to the medical practitioner should not be less than the fee payable by the Ministry of Pensions for identical or similar services, viz., £2.2 a session. The Representative Body adopted the following motion: That the Representative Body is of opinion that the suggested remedy for existing financial straits of hospitals, namely, to demand contributions in aid of their maintenance from the patients, fundamentally alters the basis of the relationship hitherto existing between honorary medical staffs and subscribers, and refers the question to the council for consideration and report.

HOW MAY THE TUBERCULOUS PATIENT
SECURE AN ARRESTMENT AND AVOID
BECOMING AN INVALID?*

BY F. M. POTTENGER, A. M., M. D., LL.D.,
F. A. C. P.,
Monrovia, Cal.

The systematic campaign against tuberculosis in America is now in the second half of its second decade. It is now time for us to take stock and see if we are accomplishing what we should; for it is only by analyzing facts that we have a basis for future progress. While it would be profitable to discuss the successes and failures of the movement as a whole and to show the great good that has come to mankind in general, as a result of the gospel of fresh air and better living that has been incessantly preached by those interested in the anti-tuberculosis crusade, I shall limit my discussion to one important clinical problem which confronts all who are trying to help those who are afflicted with tuberculosis to regain their health, viz., how can they regain their health and again be useful members of society.

This theme forces the discussion of two questions; first, how to regain health; second, how to remain healthy; and carries with it an imputation that the ultimate results gained from the treatment of tuberculosis are not all they should be.

The case may be stated as follows: 1, Observation of those who are treated for tuberculosis, whether in the home, the dispensary, or the sanatorium, reveals the sad fact that the total percentage of those who secure an arrestment or healing of their processes is disappointingly small; 2, of those who are pronounced arrested or healed the number who relapse is disappointingly large; 3, of those who remain well as far as their tuberculous infection is concerned a disappointingly large number are in a state of invalidism or semiinvalidism which incapacitates them for taking their place in the social and industrial world. Each of these statements deserves full and free discussion, which should be preceded, however, by certain statements regarding tuberculosis, its general characteristics and its curability. Many of the shortcomings in the diagnosis and treatment of tuberculosis depend upon a failure to understand the essential nature of the disease, and the manner in which it affects

the patient; or if understood, a failure to act in the interest of the patient at the proper time.

Tuberculosis is a chronic infectious inflammatory process in which there is a long interval between the time of infection and the clinical manifestation of the disease. While tubercles undergo much the same type of evolution that is noted in a boil on the body surface—implantation followed by induration, necrosis, rupture, and healing—these changes take place extremely slowly, taking weeks, months or years for the cycle instead of a few hours or a few days. Often the stage of necrosis and rupture fails to appear, the process remaining as an induration for a long period and then changing into scar. During this long period there may be a gradual progressive extension of the infection or there may be intermittent extensions. The infection, however, does not become a clinical disease until sufficient toxins have passed out into the blood stream, and, acting through the nerves and endocrine system, interfere with the normal physiological equilibrium of the various organs and structures; or, until the process acting locally on the nerve endings in the areas of inflammation, causes reflex disturbances in physiological equilibrium; or, until it produces some local change which makes its presence known, such as pleurisy, sputum or blood spitting.

It is evident that a disease process which shows such resistance to the healing forces of the body as tuberculosis, offers chances of healing somewhat in proportion to the extent of the infection and the pathological condition of the tubercles; and further, that the chances of the disease spreading are largely in proportion to the degree of pathological activity in the individual tubercles, the danger being much greater in necrotic ruptured tubercles than in those which have reached only the stage of induration. Whereas, limited infiltration prior to the time that the tubercles undergo necrosis offers a fair opportunity for the process to become quiescent, quiescence occurs much less readily when necrosis has occurred and especially when the process is at the same time extensive. Infection is usually present in the individual in a quiescent or semiquiescent condition long before it is recognized. Unfortunately, it may not produce symptoms; or, if present, they may not be recognized; so the disease as met today is often an advanced destructive process.

From the very nature of the case it must be evident that disappointments in results of treatment

* Read before the sixteenth annual meeting of the National Tuberculosis Association, St. Louis, April 22, 23 and 24, 1920.

are unavoidable. 'But if these disappointments are greater than they should be it is our duty to find out why. A study of reports in the literature, particularly those from institutions, shows a wide variation in the number of cases which are discharged as arrested. It also shows wide variation in the character of the patients as to the stage of the disease, and the length and character of treatment carried out.

The fact that practically all patients who manifest their clinical symptoms in adult life have been in stages alternating between activity and arrestment prior to the time that it was recognized clinically, should suggest the possibility of healing in a very large proportion of early clinical cases when the patient's resistance has been first overcome; and, if such a desirable result is not being produced it must be because the methods of treatment available are not sufficient, or because patients are not given or do not take advantage of a treatment which is capable of producing results.

That tuberculosis is not being treated during this early favorable stage is apparent to all who will observe. Sanatoria and dispensaries are filled with advanced cases. Specialists who should be best able of all members of our profession to cope with this disease successfully are spending most of their energy fighting a losing fight with patients far advanced in the disease. While they are often successful yet they might nearly always be successful if only they guided the patient in the early stages of his disease. This has been the tuberculosis specialist's lament for the past quarter of a century. How much longer it shall continue to be, will depend upon the impression which the truths about tuberculosis make upon the profession and upon those who are afflicted.

The tuberculous patient must not be permitted to become a consumptive. It is only a step from the early, limited, apparently innocent process to the advanced, extensive, dangerous one. The early lesion carries with it all of the possibilities of the advanced one; and unless checked, may at any time assume dangerous proportions. That a small infiltration which has scarcely yet made sufficient disturbance in the normal physiological working of the human machine to make its presence known carries with it a threat or a present danger to life, is not easily appreciated by those who are not more than casually interested in this disease. Unfortunately, this confuses most laymen and an all too large number of medical men. What specialist has not had the experience of making an early diagnosis of tuberculosis at a time when a life could be saved, and having it contradicted by some good doctor, and then seeing the same patient after a few months, or sometimes after a few years, go down to death with advanced tuberculosis. The specialist knows that months, and at times, years intervene between different periods of activity in tuberculosis. The patient and the good doctor too often do not know this, but expect active disease to follow at once when the process is sufficiently advanced for a diagnosis to be made; and when it does not, they too often foolishly assume that the diagnosis was in error. I do not desire to be understood as assert-

ing that specialists never err in diagnosis, but they should not err as often as other members of the profession. Infallibility, however, must not be expected.

Unfortunately there is, as yet, no specific cure for tuberculosis, and our success in therapy must depend upon measures which imitate or aid the patient in his own natural defensive methods. We are forced, too, to apply them at a time, as is evidenced by the activity of the process, when, at least temporarily, the body, unaided, has failed to win its fight. The earlier we come to the aid of the patient the more surely can we help him. While it is possibly true that the patient with an advanced lesion has a higher degree of immunity than the one with a smaller one, yet the advanced lesion produces a more serious local injury which cannot be so readily repaired; and a more serious general impairment of function which weakens the general resistance of the patient; and these together make healing difficult or impossible.

It is a selfevident fact that a satisfactory result can be obtained in a large proportion of those afflicted with tuberculosis only in case they receive treatment when the disease is limited in extent, and before severe pathologic changes have taken place. The fact that our agencies for the treatment of tuberculosis are so generally engaged with advanced cases largely defeats the efficacy of the effort and at the same time furnishes a basis for the persistence of the harmful pessimistic psychology which unfortunately has surrounded tuberculosis since the dawn of therapeutic endeavor. While early diagnosis and early intelligent treatment will restore most tuberculous patients to health, the opinion of the success of therapeutic results today is based too largely upon the treatment, often poorly carried out, of advanced cases in which defeat is conceded as sure and positive in a large proportion before it is undertaken. This fact has done much to discredit the treatment of tuberculosis.

While the imputation that the number of tuberculous patients who attain an arrestment of their disease process is disappointingly small is based on fact, it should in no way discourage therapeutic effort. It should, however, spur on all who are interested in the treatment of this disease to increased effort to secure early diagnosis and immediate intelligent treatment. Then and then only can acceptable results be obtained.

The large proportion of relapses among those who have secured an apparently satisfactory result is another disappointment to clinicians as well as to patients. This danger must always be recognized and guarded against in all ways possible. All other factors being equal the danger of relapse is in proportion to the severity of the pathological process; which again emphasizes the importance of early diagnosis and early treatment. Probably the next most important factor which contributes to relapses is inadequate and insufficient treatment. The chronic nature of tuberculosis must always be borne in mind; so must its resistance to the defensive forces of the body. It must further be borne in mind, if the disease has existed for any length of time, that it so injures its host as to reduce his fighting power.

Whether or not an arrestment shall be attained and maintained depends greatly upon the patient's own powers of resistance; a vague expression, to be sure, but one that has come to be understood as meaning the ability of the body cells to functionate in such a manner as to be able to check attempts at multiplication on the part of the bacilli and extensions of the process to new tissues, and to promote tissue generation in the form of scar in the areas of disease. The greater the extent and the more active the process the greater the disturbance in the physiological processes of the body of the host and the longer the time required for the establishment of equilibrium.

While an individual tubercle might pass through all the changes from implantation of bacilli to tubercle formation and conversion into scar in a few weeks' time under circumstances favorable to healing, in a process so extensive as to produce symptoms and cause clinical tuberculosis, even in an early stage, tubercles are massed together in such a manner as to preclude this rapid healing. Instead of weeks, under most favorable circumstances, months are required for a favorable pathological transformation; and, during all this time it is necessary that the patient's fighting power be adequate not only to prevent further growth of bacilli and extension to new tissues but so to encapsulate the bacilli present that further activity is impossible. To this end hygienic working colonies should be provided for those who are financially dependent where patients with arrested disease can work according to their strength after their discharge from sanatoria.

Patients are often unable, for financial or other legitimate reasons, to carry out the necessary régime long enough to secure an arrestment; at other times, they feel so sure of winning that they cannot see the necessity; or they yield to some desire which at the time seems paramount. The physician will be successful in treating tuberculosis just to the extent that, knowing the character of the process and nature's way of overcoming it, he is able to keep up his own interest in the patient and to secure the patient's cooperation for the time necessary for the pathological process to be transformed into scar and the patient's physical, psychological and nervous equilibrium to be restored to normal or as nearly to normal as possible. The length of time required for this is far longer than is usually believed. In early cases this may take two years or more, and in advanced cases the time is proportionately longer. The time also differs in different individuals, and they must be made to understand this. It is natural and usual for each one to feel that his case is one of the most favorable ones and that he will get well in the minimum time; but usually such is not the case.

We must regard the psychology of the patient. With this in mind it is necessary to impress upon him first that tuberculosis heals slowly and second that it is an individual matter, healing faster in one person than in another, both because the disease process differs in different individuals and because the fighting power of patients, including both natural resistance and willingness to cooperate, differs. It should be further impressed upon him that it will be a matter of two or three years or

more before healing will be completed, and that he will have to take extra good care of himself during that time. We have found psychologically as well as from the viewpoint of results, that it is best not to keep the average patient too long under treatment at one time, but to have him at two or more periods. In our early work we noted that relapses which took place usually occurred from three to nine months after the patient left off treatment. We noticed too that there was a relationship between the tendency to relapse and the degree of healing which took place prior to discharge, the stage of the disease, and the faithfulness with which the patient followed the necessary régime. It was then that we saw that it was a duty as well as an absolute necessity that the physician gain the confidence of his patients to such a degree that they would be willing to cooperate long enough to get well. It is now our rule to treat our patients until physical exercise, such as walking from one to ten miles, according to the condition of the patient, produces no toxic symptoms, and until we feel that the chest signs are no longer those of a nature which are likely to reactivate and spread. The patient is then allowed to interrupt treatment, following out a restricted régime with only occasional supervision for a period varying from three to nine months, when he returns for another period of strict guidance. In far advanced cases a second period of rest followed by a third period of strict guidance is adopted. The results of this method, which is fashioned somewhat after the *Etappen methode* of tuberculin treatment followed by Petruschky, has been most satisfactory to both patient and physician. It furnishes an opportunity for applying the healing measures under favorable psychological conditions long enough for arrestment to occur; and in this way reduces relapses to an unavoidable minimum.

The third criticism of the results of treatment that I desire to discuss is that of those who secure and maintain an arrestment of their tuberculous process, a disappointingly large number remain in a state of invalidism or semiinvalidism which makes it impossible for them to take their places in the social and industrial world. Again we must admit the truth of the criticism; and it is our duty to endeavor to find some method of overcoming it.

Several causes for such a state of invalidism are apparent.

1. Many are so seriously injured by the disease that they are invalids before the treatment is instituted; or become so later. This can be overcome to a large extent by earlier diagnosis and earlier treatment.

2. The struggle to regain health, with its attendant sacrifices and disappointments, makes such a psychological impression on the patient that he fears that any exertion physical or mental may lower his resistance and allow the disease to again become active. The length of the struggle, with its consequent deleterious psychic impressions, can be relieved partly by treating the disease early instead of when advanced. Another factor of importance is that of inculcating a positive philosophy into these patients, telling them what they can do instead of

what they cannot do. There are too many don'ts for consumptives and not enough do's; the result of which teaches them to fear all acts which call for more than a minimum of energy.

A very important factor in preventing invalidism is to restore the patient's nervous and psychical equilibrium and his physical vigor and resistance to a high degree before discharging him. This latter must be done after all activity is over when exercise will not be attended by toxemia or other annoying symptoms. I have no patience with the idea of making patients work or allowing them to be up and around, when their disease is active. It is contrary to sense and proves to be the factor which prevents healing in a great number. Toxemia should be eliminated as soon as possible because of its deleterious influence upon the body functions and because of its harmful psychic effect. Strength must be conserved to fight the infection in every way possible. If the patient exercises when the disease is active both of these principles are disregarded. With rest during the period of activity, the time of treatment is shortened; and with graduated exercise, always within the patient's strength and always short of tiring, pursued until the patient has built up a strong physical resistance, the danger of invalidism will be largely overcome, because the resistance is built up under the direct guidance of the physician.

Many do not seem to recognize the value of rest as a therapeutic measure and blame it for making the patient overcautious and producing invalidism. This is unfair. If it produces this result it is because it is incorrectly applied and because other measures such as exercise at the right time and the psychology of the patient are neglected.

As clinicians we must admit the truth of these criticisms; but, on the other hand, we must insist that they are largely remediable. As Dettweiler so aptly suggested many years ago, the cure of tuberculosis is a matter of character and the pocketbook. It is only a comparatively small number of people who, unaided, are able to finance the long treatment necessary for early tuberculosis, let alone that of advanced. It may be further said with equal truth that few people, unaided, possess sufficient strength of character to persist in a régime of selfdenial and selfcontrol long enough to get well of their tuberculosis, either early or late.

Fortunately financial aid is being secured for large numbers through private philanthropy and public recognition of the tuberculous patient's rights. At the same time it will be a long time before such aid will be adequate. It must be remembered, however, that one's resources will go two or three times further in financing the treatment of early tuberculosis than they will in financing advanced tuberculosis; and the chances of making a useful citizen who can take up his or her burden in the home or state are infinitely greater.

Unfortunately character is something which cannot be bought. Fortunately, however, it may exist as well in those not possessed of means as those who are. Whether it shall stand the test and be able to carry the patient through the long course of treatment until an arrestment has been secured

and the patient restored to usefulness will always depend largely on the physician who guides the case; but to a certain degree upon all those who come in contact with the patient. Not only must the physician furnish the proper psychology for the patient, but also for the attendants as well. This is a considerable burden, but one necessary to be assumed.

As the financial burden increases with the time of treatment extended, so do the psychological problems in the handling of the patient. The remedy for both of these difficulties as far as they can be remedied is early diagnosis and immediate intelligent treatment.

The just but unfortunate criticisms herein discussed may all be largely corrected in the following manner:

1. In order to increase the proportion of arrestments and prevent relapse early diagnosis and immediate application of an adequate treatment are essential; and further, such treatment must be continued long enough to afford the patient's defensive forces the opportunity of not only checking the power of the bacilli to grow and multiply but also to repair the damage done to the patient.

2. The patient, if treated early, will not be so prone to become an invalid, because: a. The disease itself has not yet proven so injurious to his anatomical and physiological processes. b. It will not have made so great and so harmful an impression upon him psychologically. c. His struggle for regaining health has been shorter and it has not taxed his finances so heavily nor has it created in him such fear of relapse.

3. If the patient is to go back and become a useful member of society the physician must prepare him for so doing. To this end it is not sufficient to arrest the tuberculous process, but it is equally important to restore his nervous equilibrium and to build up his physical strength so that he can endure work and to arm him with a positive optimistic psychology which will help him to readjust himself to the hostile forces about him.

THE ASTHMA PROBLEM*

By ALBERT VANDER VEER, JR., M. D.,
New York,

(From the Department of Medicine and Bacteriology of Cornell University and the Clinic of Applied Immunology, New York Hospital.)

For many years the problem of asthma has been one of the most difficult in medicine. In fact, it is only within the last decade that any marked advance in its solution has taken place. Until this late date the usual attitude toward the asthmatic patient was summed up in the oft quoted remark, "Of course it's a very distressing disease but no-one ever dies from asthma." Cold comfort this for the poor suffering patient who might go from doctor to doctor, from allopathy to homeopathy, to osteopath and chiropractor, always in pursuit of that mythical "friend of a friend of mine who was cured by —," to be met in the end by the remark quoted above. No wonder he finally gave up try-

* Read before the Albany County Medical Society, March 10, 1920.

ing and accepted his fate with what resignation he could, branded as a neuropath by those of us who could do nothing for him, and bearing with his physical ills the half contemptuous pity of those splendid, healthy, normal individuals who were not neurasthenic and had no asthma. And yet at times a ray of hope broke through his cloud of despair. An occasional authenticated case of cure or relief came to his attention. Some asthmatic moves from Maine to Arizona and is free—or else moves from Arizona to Maine. He gives up farming to become a banker, or carries a lucky penny in his pocket, and our patient tries the same scheme with renewed hope, but it doesn't work for him and another fond hope is blasted.

I well remember, in my medical school days at the College of Physicians and Surgeons, Dr. James, professor of medicine, telling us of a colony of asthmatics who could live only around Second Avenue and Thirteenth Street, New York. As soon as they came above Forty-second Street they had an attack. Many tales as strange as this are current and they explain our readiness to dub the asthmatic as a neuropath and our insistency that if he would only get hold of his nerves and make a man of himself he would cease to suffer. With our more recent knowledge how easy it is to explain some of these apparent inconsistencies.

It is time something was done to help these sufferers. There is probably not one of us who has not, at some time, sat near a patient suffering from an acute attack of asthma, suffering with him in his distress and feeling powerless to help, or, worse yet, able to help and not daring to. We all know that the injection of a small dose of morphine will ease the labored breathing and bring comfort to the patient—for a time. We also know that these attacks will come again and again and that the morphine injection will bring less and less relief with a larger and larger dose until finally we have two evils to fight where before there was but one.

The first real step of progress was made when Meltzer (1) brought forth the hypothesis that asthma was an anaphylactic phenomenon. This was in 1910 and succeeding steps have come rapidly until now it is rare to read a medical magazine which does not contain at least one article on asthma or hypersensitiveness.

In 1911 Freeman and Noon (2), in England, published a short article on the treatment of hay fever by injections of pollen extract, which was apparently the first step in the scientific treatment of hypersensitiveness. Their work was soon followed by similar experiments in the United States. Much of the pioneer work in this line in America has been done by Dr. R. A. Cooke, of New York, with whom I have been associated for ten years, and most of the statistics on which this paper is based have been drawn from his case records.

Starting with the asthma associated with hay fever the work has been a steady assault on the asthmas due to hypersensitiveness to other substances until now I think it is fair to estimate that about seventy per cent. of all asthmas (of course in this paper I exclude the so-called cardiac and renal asthmas) may be diagnosed by careful

work, and in this disease the diagnosis, as a rule, is more than half the battle.

DEFINITION AND CLASSIFICATION.

The following definition and classification of asthma, with postulates which must be fulfilled before one may assume the allergic condition of an individual to any substance, are taken from the article on bronchial asthma by Cooke in Tyson's *System of Medicine*.

Definition.—Bronchial asthma is a condition characterized by dyspnea, both inspiratory and expiratory, especially the latter, due to bronchial spasm and edema of the bronchial mucous membrane. It may be acute, subacute or chronic. The term bronchial asthma should be restricted to that condition which is the result of an allergic reaction.

Classification.

- | | | |
|---------------------|--|--|
| 1. Allergic. | a, by inhalation..... | { Animal dander.
Pollens.
Sachets and perfumes. |
| | b, by ingestion..... | { Drugs.
Foods. |
| | c, by absorption from focus | { Bacterial proteins. |
| | d, by subcutaneous or intravenous injection | { Therapeutic sera. |
| | | { Acute bronchitis
Chronic bronchitis and emphysema.
Pulmonary tuberculosis.
Cardiorenal disease.
Thymic enlargement.
Enlarged bronchial glands.
Reflex bronchial spasm. |
| 2. Nonallergic..... | | |

The relative size of the groups under this classification may be judged from the following figures. I had hoped to have a large group of cases covering the work done in 1917, 1918 and 1919 but owing to the short notice on which this paper was written I am only able to give the figures for 1917, a total of 143 cases. Of these, eight were seen but once or twice and are rejected as giving insufficient data for a diagnosis. The 135 remaining cases were divided as follows: Pollen 52, or 38.5 per cent.; mixed 19, or 14 per cent.; animal 12, or 9 per cent.; bacterial 11, or 8 per cent.; food 2, or 1.5 per cent.; undiagnosed 39, or 29 per cent.

A word in regard to this classification. A large number of patients will give skin reactions to two or more substances in different groups, for instance to a pollen, several foods and possibly some animal dander, and yet the only complaint may be asthma occurring with hay fever in September. This is therefore classed as a pollen asthma and not mixed, although giving skin reactions for other substances. The patient is said to be potentially allergic to the other substances but for some reason they do not come in sufficiently close contact with the bronchial mucous membrane to set up a reaction. At any time, however, clinical symptoms may result from such substances and the patient should be warned of that fact when the diagnosis is made.

The two postulates, formulated by Cooke, that must be fulfilled before we may assume that any substance is etiologically important in a case of hypersensitiveness, are as follows:

1. Hypersensitiveness must be demonstrated either by, a, a positive local reaction, cutaneous or ophthalmic, or b, the original allergic manifestation must be artificially reproduced at will on introduction of the substance, either inhaled, ingested or subcutaneously injected.

2. It must be shown that the individual comes in contact in some way with the suspected substance in order to permit it to act as an etiological factor.

DIAGNOSIS, TREATMENT AND PROGNOSIS.

I shall now take up in detail the diagnosis, treatment and prognosis. First and foremost a careful history is essential. This should include the place and time of year of the first attack, if known, and the general course of subsequent attacks. If the asthma is confined to one season of the year, summer or fall or summer and fall, particularly if it occurs with hay fever, it is almost surely a pollen asthma. This premise is strengthened if it occurs in localities where pollen is abundant, as in the country, and is absent or minimized at the seashore, on shipboard, or in localities where pollen is at a minimum. It is well to remember that there is no rag weed in Europe and very little in Canada and northern United States: Hence the asthmatic victim of rag weed pollen will state that he is free in those localities. Grass pollen, which causes hay fever and asthma in May, June and July (in this zone) is present in Europe, Canada and most of the United States. Therefore the patients sensitive to grass pollen will have their hay fever and asthma no matter where they go for relief. In patients with hay fever asthma is likely to develop during a particularly severe attack but they usually suffer only at the height of the season and recover rapidly after the disappearance of the pollen unless a secondary bacterial infection is acquired, of which more will be said later.

The history should also take into consideration animal hypersensitiveness. Many people know that they have such a hypersensitiveness to horses and that proximity brings on an attack of asthma or hay fever, but few realize that cats, dogs, and other domestic animals may be the cause of their trouble. The mere presence of such an animal in the house, continually shedding its epithelium, may cause much discomfort to a hypersensitive patient even if he shuns intimate contact with the animal. An illustration of this is furnished by a lady who knew that she was hypersensitive to cats but had several in the house, avoiding close contact with them. She suffered from asthma but was free at Atlantic City, attributing the freedom to the change in climate. Removal of the cats plus a thorough house cleaning for a week entirely removed the trouble.

It is well to get a careful history of the location of the attacks. A case in point is that of a boy who had lived in Coney Island for nine years without any trouble. He then moved to a new house where he and his parents lived in two rooms. Within a few days he started to have asthma which continued intermittently for two years. He came to New York and spent ten days in a hospital where he was free. The next month at home he had it

continually. A week at a relative's house in the Bronx and he was free. The asthma returned when he went home. The father of the boy wanted to move from Coney Island as "the climate did not agree with him there," but from the history it was apparent that the causative factor in the asthma was inside those two rooms. Careful investigation and testing revealed two pillows stuffed with rabbit hair to which the boy gave marked skin reactions, and removal of those two pillows removed his asthma completely with no further treatment. This of course is an extreme case but it illustrates how valuable a careful history is in tracking down the offending substance.

Practically all asthmatics are bothered by cold, windy days or damp, muggy weather but these factors should be recognized as nonspecific and not as the specific exciting agents. Like epilepsy, the more asthma a patient has, the easier it is to set up an attack, and conversely, if we can remove the main exciting cause and give the patient freedom for some time, mechanical causes will not, of themselves, excite an attack.

It is often possible to get a history of gastrointestinal disturbances preceding or accompanying the asthma and here it is necessary to find out if the patient has noticed any particular articles of diet which may cause trouble. Such a history must, however, be accepted with caution and subject to future confirmation by tests as we have often found patients' own deductions in this matter most erroneous. It is not unusual to be told that certain articles of diet at times give rise to symptoms and at other times can be eaten with impunity. We know that the skin tests with many foods occasionally give us positive results at one time and negative at another, so it is probable that there is some other element which enters into the situation here, constipation, rapid absorption, certain combinations of food, we know not what it is, and thus gives rise to such differences in the action of foods.

The family history should be carefully elicited. It has been shown (3) that hypersensitiveness is probably transmitted as a dominant characteristic according to the Mendelian law. In a series of 621 cases of human allergy it was shown that if both parents were hypersensitive, 67.5 per cent. of the children would exhibit some clinical form of hypersensitiveness (not necessarily the same as either parent) and that this would appear before the fifth year as a rule. If one parent is hypersensitive sixty per cent. of the children will show hypersensitiveness and the height of the curve of incidence will be before the fifteenth year. In those cases with a negative family history the height of the curve was between the twentieth and twenty-fifth year. In 504 cases with satisfactory history there was a positive antecedent, direct or collateral family history in 48.5 per cent., which contrasted strikingly with a positive history of hypersensitiveness of 14.5 per cent. in the antecedents of seventy-six normal controls. It is estimated that hypersensitiveness occurs in about ten per cent. of all people.

After a careful history has been obtained the patient should be tested against substances to which

he may react. The basis of this test is the fact that where any part of the body is hypersensitive to a foreign substance, as the bronchial mucous membrane in asthma, the nose and eyes in hay fever, the skin in urticaria and angioneurotic edema, there is usually a corresponding hypersensitiveness of the skin to such substance. This is not an invariable rule but occurs in the vast majority of cases. The usual way to make such test solutions is to grind up the substance to be tested in salt solution (with a little carbolic acid added as a preservative), alternately freeze and thaw several times and then filter. Such solutions will keep for a long time if placed in a cool atmosphere when not in use and are not easily contaminated, if ordinary precautions are used. Such test solutions are now put out by many commercial drug houses.

The testing is conveniently done in groups—thus the inhalation group consisting of the pollens, animal emanations, sachets and dusts—the foods—the drugs, etc. Of these the inhalation group is the most important. The solution is injected intradermally (not subcutaneously) into the skin on the outer surface of the upper arm, using a one c. c. tuberculin syringe and a fine needle. A separate syringe is, of course, used for each solution. A minute quantity is sufficient, about one fiftieth c. c. which raises the skin in a wheal about one quarter inch in diameter. From eight to thirty of these tests may be done at one sitting providing the patient is not too sensitive. Here I wish to emphasize a word of warning. Where you have reason to believe the patient is very sensitive do only a few tests at a time. If a patient is hypersensitive to three or four different substances, particularly if these are pollens or animal emanations, it is quite possible to excite an attack of asthma or urticaria from these skin tests alone. Therefore a second word of warning—do not perform any of these tests or give any injections without a bottle of epinephrine at hand. If a reaction develops it is easily and safely controlled by a subcutaneous injection of one half to one c. c. of epinephrine repeated every ten or fifteen minutes if necessary. Reactions will occur. After ten years of this work we are still getting reactions at unexpected times due to the unknown hypersusceptibility of some people but with the prompt administration of epinephrine I have yet to see any reaction which was more than a passing discomfort. I have seen many however, which would have been most uncomfortable, if not even dangerous, but for the prompt and sufficient administration of epinephrine. As to the latter, I have never seen any bad effects from an overdose except a nervous, shaky, chilly feeling which passes off in a longer or shorter time. I do not want to overemphasize the dangers of this method of diagnosis and treatment but if you will bear in mind this precaution you will save your patients and yourself a most uncomfortable hour which may come when least expected.

The skin reaction, if positive, will show in from five to fifteen minutes and in an urticarial wheal varying in size from a dime to a silver dollar or larger. The readings commonly employed are, negative (no enlargement of the original wheal);

slight (about the area of a dime); moderate (between slight and marked); and marked (varying in size from a nickel up, with pseudopod formation). There is usually an area of redness about the wheal and, with the marked reactions, almost invariably a sense of itching. The reactions usually begin to fade away after fifteen or twenty minutes but if many tests are done and several are positive the arm may remain red and swollen for twenty-four hours. This is in no sense an infection and the patient should be reassured and told to apply cold cloths to take away the itchy feeling if it is uncomfortable. Where many tests are to be done it is well to alternate the arms and possibly allow a day or two to elapse between tests. Adults rarely mind the discomfort when they are anxious to discover the cause of their trouble but it is difficult to perform many tests on children and it is therefore necessary to eliminate by the history as much as possible and only test for what is felt to be absolutely essential. Fortunately their diet is much simpler than adults and as milk, eggs and wheat are the chief offenders in their cases it is often possible to get a good result with the minimum of testing.

As to the extracts used, where the case is a pollen asthma it is rarely necessary to use more than the grass pollen (for June and July cases) or the rag weed pollen (August and September). Very few people are hypersensitive to other pollens to a degree to cause them trouble, although they are convinced that roses, goldenrod and other flowers are at fault. After many years of testing and treating we have discarded the use of these other pollens except in a very few instances.

From the skin tests it is possible, in a rough way, to judge somewhat of the degree of hypersensitiveness of the patient—the more marked the reaction the more susceptible the patient, and the smaller the dose needed to immunize. I do not believe, however, that it is possible to determine absolutely the size of the dose by measuring the size of the wheal.

Eye tests should also be done. A drop of the same solution placed in the eye will often give a reddening of the caruncle and conjunctiva with a sensation of itching and may cause sneezing and blocking of the nose on the same side by running down the nasal duct. It is easier to judge of the hypersensitiveness of the patient by his reaction to solutions of different strengths in the eye than by the skin reactions.

Horse epithelium is the most important of the animal emanations (which are, of course, quite different in their action from the animal sera), next in importance being cat and dog. Other animal dander for which tests should be made are rabbit (used in stuffing pillows and as a fur), cow, sheep and the feathers of chicken, duck and goose (used in pillows). Animal sera are of less importance but a test should always be made with horse serum and, if positive, the patient should be warned of the danger, to him, of diphtheria or other anti-toxin injection.

The number of skin tests to be done varies with the history obtained. In a clear cut pollen asthma it is unnecessary to subject the patient to tests with

all the foods and other substances. Here you are only interested in confirming the rag weed or grass pollen hypersensitiveness and its degree. Where the history is irregular it is necessary to test with animal emanations, sachets (as well as the pollens), food, and in fact all the preparations at your command.

Beside the skin tests it is essential to make a complete physical examination in all cases. This will enable you to rule out cardiac and renal asthmas, mediastinal growths, and possible foci of chronic infection located in sinuses, teeth, or the gastrointestinal tract. Of these the sinus infections are the most frequent and important and a diagnosis of such trouble should be followed immediately by proper remedial measures.

The blood count in asthma shows little that is characteristic except an increase of the eosinophile cells in the differential count. They are usually between four and ten per cent. but may go as high as sixty or seventy per cent. As yet we do not know the significance of this increase but its occurrence points to an asthma due to hypersensitiveness rather than to one of renal or cardiac origin.

TREATMENT.

The first thing is treatment of the immediate attack. Here our chief reliance must be placed on epinephrine used hypodermically. From five to fifteen minims of this drug repeated every half hour or so will control the great majority of asthmatic attacks, the relief lasting from a few hours to a day or more. I think this drug is too sparingly used, because of the impression that it raises blood pressure and eventually causes chronic hypertension. This is not true and you may easily prove to your satisfaction that epinephrine, administered during an attack of asthma, actually lowers the blood pressure from ten to thirty or more points by relieving the bronchial spasm. I have seen patients who have taken epinephrine for many years in considerable doses and who do not exhibit hypertension or any ill effects from it; nor, as a rule, do they have to increase the dose. Incidentally I may mention that it is of equally great value in other manifestations of hypersensitiveness such as urticaria, angioneurotic edema and those rare cases of shock following the ingestion of food or drugs to which a patient may be allergic. It is one of the few drugs which can be depended on to work and should be in every practitioner's armamentarium.

Morphine has been used for the acute attacks. Personally I have a great dread of it in such a chronic condition as asthma. It will, of course, relieve the immediate condition as well as epinephrine but the danger of forming a habit is too great and it should be used only in cases of the most urgent need. For milder attacks there are a number of pastilles, powders and cigarettes on the market, most of them with a base of stramonium leaves, which are very valuable and should be used to give the patient relief. Atropine may be given in doses of 1/200 to 1/75 of a grain as indicated. It can be given by mouth or hypodermically and is a valuable aid. Benzyl benzoate in doses of twenty to thirty minims four times a day has lately been highly recommended. What little

experience I have had with it has been most disappointing, but in view of the good reports from other observers I think it is worthy of a thorough trial.

The treatment of the underlying condition, of course, depends on the history and results of the examination and tests. Where the exciting cause can be eliminated from intimate contact with the patient, this should be done. Where this cannot be done the patient should be immunized against the exciting cause. To illustrate: Where the patient is hypersensitive to one or more articles of food, these should be eliminated from his diet. It often happens that after abstaining for a time he is again able to eat such foods in moderation without trouble. This is particularly true with children who are hypersensitive to egg or milk proteins. We have records of a number of such cases, hypersensitive in early childhood but now able to eat milk and eggs in adult life, without any trouble. This is in marked contrast to hypersensitiveness to animals and pollens which is very likely to continue during the life of the patient.

In the case of the boy hypersensitive to rabbit hair the treatment was simply to remove the pillows stuffed with such hair and to warn him of his enemy for the future. In cases of cat and dog hypersensitiveness, it is easy to immunize against the dander but as the treatment must be continued indefinitely it is wiser to remove the offending animal. It is not sufficient to stay away from the cat or dog—it must be entirely removed from the house and then all the rooms must be carefully cleansed several times to get rid of the dander scattered about.

In pollen hypersensitiveness it is ordinarily impossible for the average person to avoid exposure during certain times of the year. For the leisure class there is always the opportunity and excuse of a trip to Europe where they may escape the late hay fever and asthma but the grass pollen cases are as much exposed in Europe as they are in this country. We must here make use of active immunization and fortunately the results are excellent, better in fact than the results of the treatment of the hay fever with which the asthma is associated. Cooke reports a series of 135 cases of hay fever and asthma treated by pollen injections with the following results:

Asthma not improved.....	5 per cent.
Asthma slightly improved.....	6 per cent.
Asthma improved	36 per cent.
Asthma absent	53 per cent.
Hay fever not improved.....	4 per cent.
Hay fever slightly improved....	5 per cent.
Hay fever improved.....	85 per cent.
Hay fever absent.....	6 per cent.

In other words the asthma was entirely controlled in over half the cases while in thirty-six per cent. more a fairly satisfactory result was obtained.

The principle of the treatment is the injection of gradually increasing doses of pollen extract at intervals of from five to seven days. Such extracts are now obtainable from many commercial drug houses. The only disadvantage in their use is that the dose is graduated to the more sensitive cases in

order to avoid constitutional reactions and hence the doses are too small to immunize completely the less sensitive persons. The results, however, are surprisingly good. In the series quoted above the extract was standardized according to the amount of nitrogen contained and this enables one to graduate the doses very exactly. All patients were tested out by eye and skin tests and their degree of sensitiveness thus determined. It takes about fifteen to twenty injections all told and the treatment should be begun, if possible, six weeks before the season. If the patient is not seen until the hay fever and asthma have actually started then he is treated phylactically instead of prophylactically. Several small doses are given on succeeding days, then at intervals of two, three and four days until the end of the season. The results in cases so treated are almost as good as those treated before the season begins. By these pollen injections the asthma is not only relieved, but the patients are, as a rule, protected against secondary infections at the end of the season which very often prolong the asthma and cough until long after the pollen factor has disappeared and also renders them much less susceptible to attacks of asthma and bronchitis during the winter months.

I wish to emphasize again the importance of bearing in mind the value of epinephrine in this treatment. We endeavor to give as large doses as possible of the pollen extract without causing a general or very marked local reaction. Occasionally the patient receives a larger dose than he can stand and within a few minutes general urticaria, asthma, or hay fever develops. These reactions can be readily controlled by one or more doses of the epinephrine and are no more than a passing inconvenience. The patient should be warned of this and reassured. If such reaction occurs unexpectedly and is not treated the patient is needlessly alarmed and often refuses to continue a treatment which seems to him dangerous.

In patients hypersensitive to animals it is usually possible to avoid exposure and thus there is no necessity for active immunization. In the few cases where it seems best to immunize it is fortunately easy to do so. These are usually horse epithelium victims. The first doses should be extremely small but after about ten injections the patient is almost always able to come in the closest contact with horses without experiencing discomfort. Injections may now be given at monthly intervals or may be discontinued entirely if the patient is constantly exposed to horses and thus keeps up his own immunity.

Hypersensitiveness to sachets is best treated by avoidance of such sachets if the patient is only moderately hypersensitive. This will give freedom except on rare occasions when brought into contact with unusually severe exposure. In some cases it may be necessary to immunize with doses of sachet extract and the results are, as a rule, very good.

Patients exhibiting an allergic reaction to drugs are extremely interesting. Quinine and aspirin are the two most frequently met with. The reaction is not like an overdose of the drug in a normal

person but a typical allergic one—asthma, urticaria or even extreme shock and may occur after a very small dose. It is well to bear in mind there are such persons, who usually say they have an idiosyncrasy to such and such a drug, for we have records of at least two dozen aspirin cases, in one of which there developed an attack of asthma lasting three weeks following the ingestion of five grains, and another patient who immediately went into shock and died in five minutes from the same amount. It is probable that some cases of unexplained sudden death are due to a hitherto unknown allergy to one of these commonly used drugs. The treatment is avoidance of the offending drug and great care on the part of the patient that he never receives a dose of it by mistake.

Many cases of chronic asthma are complicated by an accompanying chronic bronchitis. Some of these will clear up when the underlying cause of the asthma is removed but many of them will require treatment for the bronchitis as well as the asthma. Here it is well to have an autogenous vaccine made from organisms recovered from the washed sputum (this must be done by a competent bacteriologist to get any satisfactory results) and these must be properly interpreted and the injections of this vaccine should be given over a long period of time. The maximum dose should be at least three to six billion and the injections should be continued for some time after the organism has disappeared from the sputum.

Local treatment for all foci of infection is, of course, essential. Polypi should be removed, sinuses drained, diseased tonsils thoroughly removed and teeth radiographed and treated. Every effort should be made to place the patient in as normal physical condition as possible.

You will frequently be asked whether a change in climate is advisable, and if you are honest with your patient and yourself the answer is usually no. I admit that the temptation is strong, when you have been dealing with a particularly obstinate case, to shift the responsibility to some other doctor living in California, or Texas, or Colorado, but the chances are that the patient will there encounter the same pollen, pillows, food, sachet, or animals which he encounters at home and if a change is made it is often just as efficacious to move next door or across the street and much cheaper. Be conscientious and persevere until you have solved the problem yourself. An exception to this rule can be made in a few cases, complicated by tuberculosis or run down by long suffering or a chronic bronchitis, who occasionally need a change in climate to build up their general health.

PROGNOSIS.

This has been touched on under treatment. The prognosis depends on the diagnosis. At the present time about seventy per cent. of all cases can be diagnosed. Over one third of these are pollen asthmas and the figures already quoted show that ninety per cent. of these patients can be made quite comfortable. Of the animal and food asthmas the great majority can be entirely relieved. The really difficult cases are those with a complicating infection, sinus, bronchial or intestinal. The larger

proportion can be relieved by appropriate treatment but they require long and careful investigation with a maximum of patience and perseverance on the part of both doctor and patient. As to the undiagnosed thirty per cent.—this class is steadily becoming smaller and I am sure will continue to decrease. Each difficult case solved is an advance. It took two months of hard work to solve the problem of the lad who was sensitive to rabbit hair but when that was achieved three more difficult cases were found to be similar and all were relieved immediately.

The word relieved is here used intentionally for it cannot be said that these patient are cured any more than a diabetic is cured who keeps within his sugar tolerance and is symptomless and sugar free. They are still sensitive to their particular substance and as far as we know they will continue to be so indefinitely. A few rare cases show complete cure, some spontaneous and some as the result of treatment but they are the exception and we do not know the reason for their recovery. However you will find that patients care very little whether you use the word cure or relieve. If they do not have asthma they are, as a rule, satisfied.

I wish to introduce here the case records of two rather typical and dissimilar asthmatics which will serve to illustrate somewhat the method of treatment.

CASE I.—Male, aged twenty-five, single, packer by occupation. Family history negative as far as any hypersensitiveness is concerned. Past history, pneumonia three times, in infancy, at seven, at eighteen; typhoid fever at seven; no malaria, tonsillitis nor rheumatism. No hay fever nor hives. No food hypersensitiveness as far as known.

Present illness.—Asthma began when he was seven, following typhoid fever and a cold. He has had it more or less ever since, all the year round. He knows that horses bother him but does not think he is affected by cats or dogs. Diet is general, including milk and eggs.

Physical examination.—Thin, rather pale. Weight one hundred pounds. Heart normal, blood pressure 120-80. Lungs hyperresonant and many coarse squeaking râles. Tonsils large and boggy. Nose and sinuses negative. Ears, right drum perforated, left retracted. Urine negative. X ray of lungs shows bronchitis of long standing, no tuberculosis. Sputum negative for tubercle bacilli. Culture shows streptococcus and Micrococcus catarhalis. Vaccine made. Differential blood count—polynuclears 43 per cent., lymphocytes 41 per cent., eosinophiles 8.5 per cent., transitionals 4 per cent., basophiles 3.5 per cent.

Skin tests extended over several days showed positive for rag weed, negative for grass pollen, positive for horse and chicken epithelium, negative for other animals, and for all foods and sachets. Later he gave positive reactions for rabbit epithelium, and some pillow feathers and the stuffing from his mattress. His treatment has been as follows, first he secured a new position as his packing job was very dusty and would tend to increase his asthma by mere mechanical irritation. He was told to get rid of his feather pillows and use pillows stuffed with silk floss instead. His mattress was

wrapped in several sheets to minimize the dust coming from it. Of course a silk floss mattress would be better but they are expensive. His rooms were carefully scrubbed and cleaned to remove all traces of the chicken feather dust. He was given injections of his autogenous vaccine and horse epithelium at weekly intervals.

Course.—The patient was first seen on October 13, 1919, and his asthma continued until the first week in November, when the injections had reached a sufficient strength to begin to give him immunity. November 14th he had some asthma following his injection. December 18th-19th slight asthma. January 4th and 10th slight asthma. None after this to date (March 10, 1920). January 17, 1920, weight 103 pounds, differential count eosinophiles 12.5 per cent.; February 14, 1920, differential count eosinophiles 8.5 per cent. March 6, 1920, weight 104 $\frac{1}{4}$, some cough, no asthma since January 10th. Is working right along.

Of course this man is not cured of asthma and if he is again exposed to the substances to which he is hypersensitive he will react as before but he knows his enemy and can avoid it. He still has bronchitis and it may take a long time to cure that, but I am sure he will get rid of it eventually. He will need rag weed injections in the summer and fall. If he can avoid the asthmatic attacks, which have been almost constant for many years, I think he will be able to stand slight exposures without treatment and without getting into trouble.

CASE II.—Male, aged forty-nine, single, iron manufacturer. Family history, negative for hypersensitiveness. Past history negative except for scarlet fever, without nephritis, and rheumatism, without heart complication. Uses alcohol moderately; hearty eater; six to eight cigars a day; no headaches; no change in weight.

Present history.—The patient had his first attack of bronchitis twenty years ago, during November and December. No asthma with it. Had a similar bronchial cold each October to December for five years. All right the next year but the following year he had severe bronchitis and asthma with it. Following this he took great precautions against catching cold and was well until 1919. In January, 1919, during a few cold days he had constriction of the throat, pain in the precordium and dyspnea. In June, 1919, he had asthma for two nights, went to Canada for two weeks and was better there, but since his return he has had asthma more or less all the time up to the present (January 6, 1920). The present attack has lasted since December 25th. He often has heart oppression. The cough is worse in the morning. The asthma seems to be the result of the bronchitis. There is no real hay fever, has occasionally had pain after eating clams but no trouble lately. One attack from eating scallops. Knows of no animal hypersensitiveness. He keeps a dog, and his iron foundry is very dusty.

Physical examination.—Weight 183 pounds. Blood pressure 118/90. Few capped teeth; the x rays of the teeth were negative. Heart, systolic murmur at apex, slightly enlarged to left, regular.

Electrocardiogram of heart normal. Lungs, signs of a chronic bronchitis and emphysema. The abdomen was negative. The Wassermann was negative. Urine 1,024, no albumin, no sugar, no indican, few hyaline and granular casts. Blood differential polynuclears 74 per cent., lymphocytes 23 per cent.; eosinophiles $\frac{1}{2}$ per cent., transitionals 2 per cent., basophiles $\frac{1}{2}$ per cent. Sputum negative for tubercle bacilli. Vaccine made containing staphylococci, streptococci, and *Micrococcus catarrhalis*, three billion to the c. c. Skin tests negative for pollens, animal emanations, sachets and dusts, marked for beef, lamb, clam, halibut, lima bean.

Treatment.—Told to omit beef, etc., from his diet and given injections of vaccine. These were started January 15, 1920, and given every five days at first. He had distressing attacks of asthma January 16th, 19th, 23rd, 28th, 29th. By this time he was getting one c. c. of the vaccine and had been on a diet three weeks. He was last seen March 10th and had had no asthma since January 29th. He still gave marked skin reactions to beef, lamb and clam.

An interesting fact in his history was obtained only after his test had been made. He said that he was very fond of beef and accustomed to eat it six or eight times a week. He also said that he was very fond of clams and that when the asthma commenced in June he was eating them frequently. At times they gave him gastric distress but at other times he ate them without trouble. His skin test was negative for them at first but markedly positive on two later occasions. It is probable that he has a cardiorenal condition as well as asthma, as but with a normal electrocardiogram and blood pressure I do not think it is very serious and restricting his meat intake will do him no harm at least. His bronchitis apparently cleared up under vaccine injections and if he experiences a second infection I think it will be wise to have another vaccine made. His is apparently a case of food hypersensitiveness with a complicating bronchitis.

CONCLUSION.

If this paper leaves you with the impression that the diagnosis and treatment of asthma are now simple matters I have failed in my purpose. It is only the rare and exceptional case where you can make a few tests, tell the patient to banish the family cat or remove such and such a pillow and be well forever after. Both you and your patient will become discouraged time and again and it will try your resourcefulness to the limit. What I do wish to make clear is that asthma is no longer the hopeless problem that it has been in years gone by. Inspire your patient with the same enthusiasm and confidence that you have in the search and keep everlastingly at it. The result in suffering relieved will more than repay your effort and the unsolved cases will become fewer as our knowledge increases.

BRONCHIAL ASTHMA IN CHILDHOOD.

By FREDERICK RAOUL MASON, M. D.,

New York,

Instructor in Pediatrics, New York Postgraduate Medical School and Hospital.

It is fairly well established that nearly all cases of bronchial asthma in children are anaphylactic in origin, although influenced by such factors as the mental state and climatic conditions. It is only by keeping this in mind that we can hope to obtain permanent results with any treatment. Bronchial asthma is only one of the many forms in which anaphylaxis manifests itself. We shall gain much valuable information by considering the phenomenon of anaphylaxis as a whole, before going into this one particular manifestation.

The following is a list of diseases which have been found to be forms of anaphylaxis and as time goes on we may have many others to add to it: Hay fever, bronchial asthma, urticaria, angioneurotic edema, certain skin diseases (or rather certain types of these diseases, such as eczema), cyclic vomiting, other gastrointestinal upsets, possibly ivy poisoning, migraines, serum disease and certain reaction to drugs (1).

What do we mean by anaphylaxis? It can be defined as an abnormal reaction of the organism to certain substances. Experimentally, it has been produced in the following manner. When a foreign protein is introduced into the organism, no reaction occurs after the first injection. If, however, we wait a suitable period of time, a second injection will produce definite changes varying with the animal used for the experiment. The first injection has sensitized the animal and the changes following the second injection are called anaphylaxis.

The following are the reactions observed in various animals: spasm of the bronchioles, urticaria, increased peristalsis, and fall in blood pressure. There is also an eosinophilia. These reactions also occur in man, although we rarely see marked falling of blood pressure, except possibly in some of the cases of death from antitoxin in highly susceptible subjects. Animal experimentation, moreover, has brought out valuable data having a practical application. Sensitization has been found to be a result of heredity, inoculation with a protein, inhalation, inunctions, intravenous injection, introduction by mouth or instillation into the conjunctival sac. From this we may see that it is quite possible to produce anaphylaxis by the improper introduction of certain foods into the diet. We know, for instance, that a number of people suffer from urticaria after eating shell fish, or strawberries, articles of food obtainable at certain seasons, and therefore there is a sufficient interval between the introductions to bring about sensitization in the individual. It is quite possible that anaphylaxis to white of egg is due to the custom of giving albumen water to infants suffering from gastroenteritis. For this reason, when a new article of food is introduced into the diet, it is best given in small quantities and in frequent increasing doses so as to prevent a possible change of sensitization. Of course there

is no doubt that a large number of patients inherit their anaphylactic tendencies. We have sufficient proof of this among our patients, a large number of whom have at least one parent suffering from asthma or one of the allied conditions. Recently there was in the wards of the Postgraduate Hospital a breast fed baby suffering from eczema. In spite of the fact that he was breast fed, and never had partaken of anything but mother's milk, he was found to be sensitized to several other foods.

Experimentally, it has been possible to transmit anaphylaxis by what has been termed passive anaphylaxis. This is accomplished by injecting the blood of a sensitized guineapig into a normal one, after which it is found that the second animal has become anaphylactic to the same proteins as the first. There are several cases on record in which, after a transfusion from the blood of an asthmatic, typical asthma has developed in a subject previously free from respiratory embarrassment. Experimentally, depending on the initial dose used to sensitize, it takes a small or a large quantity of the protein to produce an attack. The same applies in the various anaphylactic manifestations in man.

Sensitizing substances cause sensitizations which are specific to that protein or to closely related ones. It is quite common to find a child sensitized to a certain food who will also react to species very closely related. Apparently it is necessary, in order to establish anaphylactic phenomena, to have a proteid which is not reduced lower than the polypeptides; recently, however, anaphylaxis has been reported from quinine and aspirin. I, personally, know a doctor who will sneeze when a box of ipecac is opened at the other end of the room and will suffer a typical attack of bronchial asthma should he get near enough to this substance.

Why anaphylaxis takes on one form more than another is hard to determine, except in certain cases of hay fever or asthma of the inspiratory type. Here we have direct contact between the sensitizing substance and the affected part of the organism. All cases have in common a disturbance of the sympathetic or autonomic fibres supplying the affected organs. It is possible, moreover, to get a combination of these phenomena, and it is not uncommon to find in a child, given egg for the first time, a severe swelling of the lips, an urticarial rash all over the body, and a marked attack of asthma will develop.

Asthma has been described as a spasmodic contraction of the bronchioles, accompanied by hyperemia of the mucous membrane, and characterized by wheezing low râles on expiration, with numerous moist, musical or crackling râles heard all over the chest. Textbooks have laid considerable emphasis on the presence of Charcot-Leyden crystals in the sputum and an eosinophilia of about ten per cent. in the blood. In children, we do not necessarily get all these symptoms and we can divide asthma into four clinical groups, which of course merge into each other and are really only degrees of severity:

1. Frequent coughing spells, which vary in duration and frequency. This type is very common in infants.

2. Frequent attacks of bronchitis, not associated with any rise in temperature. These two types are rarely recognized as asthma.

3. True bronchial asthma attacks. These are fairly easy to diagnose. During the interval the patient feels perfectly well, but on auscultation a few musical râles can sometimes be heard in the chest. Immediately preceding the attack there is often irritability and headache. When the attack is severe, the patient sits up and grasps some firm object, the face is pale, and the lips, fingers and eyelids become livid. The expression is anxious, there is difficulty in breathing and limited expansion of the chest and the chief difficulty appears to be in expiring air. The respirations, for this reason, are slowed down in number to ten or twelve. Inspiratory sounds are short and soft, expiration is long and accompanied by a low wheeze. The accessory muscles of respiration are brought into play and to help this, the shoulders are raised. On percussion hyperresonance is heard over the chest. In older children, the area of cardiac dullness is diminished, although there is often dilatation of the right side of the heart. On auscultation, the expiratory sound is prolonged and wheezing and sonorous râles are heard all over the chest.

4. Constant asthma.

In all cases the essential feature is a recurrence at intervals of difficulty of respiration or cough, independent of any infection of the air passages.

There are, therefore, many diseases which may simulate bronchial asthma and it is well to eliminate these before making a positive diagnosis. The more common are: chronic bronchitis, whooping cough in infants, and reflex causes. The reflex causes can be divided into mediastinal enlargement, foreign body in the larynx, bronchi, lung, ear and esophagus, and possibly worms in the gastrointestinal tract. All these can be determined by either the direct examination or the x ray.

Mediastinal enlargements are rather frequent, enlarged thymus being perhaps the most common. This is, as a rule, characterized by coughing spells, appearing shortly after birth and made worse by flexion of the chest; there may or may not be a harsh inspiratory sound and râles in the chest. Percussion of the thymus is of little value and apart from the history, the x ray is the only reliable aid to diagnosis, beside being the easiest and best mode of treatment. Enlarged mediastinal glands, usually tuberculous, often cause coughing spells. These are demonstrated by the d'Espine sign, and the x ray. The Von Pirquet test will help to decide in a tuberculous case. We must not forget that occasionally Hodgkin's disease, or leucemia, may affect these glands early, but this is a remote possibility. Occasionally congenital laryngeal stridor, laryngismus stridulous, and retropharyngeal abscess may be mistaken for bronchial asthma, and it is well to keep this in mind. Once we have decided that we are dealing with a true case of bronchial asthma, certain phases in the history should be looked into, as likely to give valuable information as to the etiology.

1. When did the first anaphylactic phenomenon develop? This may immediately put us on the trail.

To illustrate: The child who had asthma following bronchopneumonia would make one think at once of a bacterial origin of the disease; or a child in whom asthma develops at the time of weaning, or when put on cow's milk, probably has a dietary cause for his affliction.

2. Time of the year the attack occurred. Asthma in winter usually suggests a bacterial cause; asthma at a definite season of the year is suggestive of the pollen of plants blooming at that particular time; or foods in season (certain fruits, for instance).

3. Location. We may find that a certain room, a certain house, or certain country localities will bring about an attack. When traced to the country or to a garden, pollens from plants come under suspicion. A certain room leads to a careful examination of the premises and perhaps the finding of the offending factor. When a whole house, the problem is less easy. It may be the particular food served in that house, a pet cat or dog, or the proximity of neighboring stables.

4. Time of the day. Cases of asthma in which the attacks occur only at night suggest something connected with the patient's bed, such as the feathers in the pillows, the hair in the mattress, or the blankets.

5. Finally, patients will often have noticed themselves, or when placed on their guard will frequently discover some factor in the occurrence of an attack. In this way we have been able to find the following variety of things to be causative factors (at least one of them): dog, cat, rabbit, horse, smell of herring, a cold, ipecac, hay, linseed, various foods, certain types of canned foods (depending on the brand), plants, pillows, stuffed animals, and skins.

In order to get a clear idea of the subject, it is advisable to group the causes of bronchial asthma under the following classification:

Inspiratory cause.—a, Pollens from plants; b, animal emanations, and animal hair or dander, bird feathers; c, dust from certain drugs.

Injected cause.—Serums (antitoxins, etc.).

Ingested cause.—a, Egg; b, milk; c, grains; d, vegetables; e, meats; f, fruits; g, nuts; h, fish and shell fish; i, spices; j, drugs.

Bacterial cause.—a, Focal infection (tonsils, teeth, gallbladder, appendix, etc.); b, bacterial infection, from the respiratory or the gastrointestinal tract.

In the children's clinic we have found that inspiratory and ingestion causes were the most frequent and that usually there were several causes not necessarily all belonging to the same group. Among the foods the most common have been egg white, milk, and wheat. Focal infection does not appear to play a very important part, although no doubt it does occur. As a rule bacteria from the nasopharynx are the source of the sensitizing bacterial protein.

In determining the etiology of the asthmatic attacks, we are greatly helped by the skin reactions. Briefly, these are performed as follows: The proteins from various foods, bacteria, and emanations are isolated, in order to be sufficiently concentrated to produce a reaction, or they can be obtained ready prepared by certain commercial labora-

tories. They are then either injected intradermally, in solution, or, which is easier, with the commercial preparations. The skin is gently scarified with a scalpel, a drop of decinormal solution of sodium hydroxide placed on it (to make a solution of the protein), and a small quantity of the protein dissolved in this. A positive reaction is indicated by the appearance of a white wheal surrounded by an area of erythema, at the site of the application of the offending protein. It often happens that asthmatics have a certain degree of dermatographia and for this reason it is wise to compare with the control. The anaphylactic wheals are usually irregular in outline and their size does not necessarily bear much relationship to the degree of severity of the disease.

TREATMENT.

As it takes considerable time to determine the provocative agent, it is necessary to do something to relieve the discomfort of the patient. The following are some of the drugs which may be used to give relief:

Adrenalin.—This, as a rule, clears up a case, or at least gives marked relief, within a few minutes, but, because of its potentiality and the fact that it loses its effect if repeated often, it should be given only during severe attacks or in cases where there is only an occasional attack, say once a year. Adrenalin can be given in doses from three to ten minims, of the one to a thousand solution, by hypodermic injection.

Benzyl benzoate.—This is a harmless antispasmodic and in many cases gives very satisfactory results. Unfortunately, it does not relieve in all cases and has the disadvantage of having an unpleasant and lasting taste. In children who are old enough I give the drug in capsules containing two minims each, four times a day. In the ten per cent. solution, the dose is half a teaspoonful four times a day for a child six years old. Increased doses do not appear to be more effective, although I know of one case in which benzyl benzoate afforded absolutely no relief when given in one half teaspoonful doses but which responded to one teaspoonful doses, when two weeks later the patient had his next attack. Benzyl benzoate is best given continuously to patients having frequent attacks, but this is not necessary in those having only occasional asthmatic attacks.

Atropine.—When given up to the physiological limit it will sometimes be of benefit, but I have never found it quite satisfactory.

Iodides.—These drugs may sometimes improve the patient's condition, and can be given in the form of syrup of iodide of iron as a general tonic in all cases.

Drugs, such as aspirin, and the bromides, are of doubtful value; nitrite of amyl or nitrite fumes are beneficial in relieving spasmodic breathing during the paroxysm.

Recently the French and British have found that peptone by mouth or by hypodermic injection prevents anaphylaxis, and they have been giving it in doses of five grams, three times a day, by mouth.

Auld has reported good results in a certain number of asthma cases by this means. We have tried peptone for a few weeks only in our clinic, so that

we are unable yet to report any definite results (2).

My own experience has been that no drug will help in all cases, but usually some one particular drug will help in each case. Of course, all these measures are merely palliative. We can only expect results by investigating the causes of the anaphylaxis and eliminating such causes as are found. This is done as follows:

The patient is placed on a diet of milk (including milk products), yoke of egg, wheat, potatoes, and one vegetable. He is then tested out for each of these proteins, and should one of them be found to be anaphylactic, it is removed from the diet list. It is also advisable to test with various feathers if their proteins are available. The patient is kept on this restricted diet for a week. Should the asthma be entirely due to food proteins, there will at once be marked improvement. The course to follow then is to test out for more foods and add them to the diet one at a time, eliminating, of course, all those giving positive skin reactions or symptoms. The skin reactions are not infallible and for this reason we should supplement each by a clinical test. It is also important to give these foods in a simple form, otherwise there may be a trace of some other substance which might precipitate an asthmatic attack.

To illustrate: We have in our clinic a child who is not sensitized to either pork, beans, or tomatoes, yet we have found, as a result of several experiments, that he will get an asthmatic attack if he eats a particular brand of pork and beans. By proceeding in this way, we are able to determine the majority of foods to which the patient is sensitized. We will take up later the treatment of these cases of a purely alimentary type.

Should we get no result after a diet limited to the few foods mentioned previously, we must next try to find some other causative factor. Inspiratory causes should be looked for. Pollens in the city can fairly well be eliminated but emanations may come from so many sources that we may fail to find their origin. It is best to give the patient a cotton pillow and mattress, to remove all skins from floors, such as bear or tiger, and eliminate pets, like canaries, dogs and cats. The proteins from dog hair, cat hair, horse dander and feathers from chickens and geese should be tested. Obviously we cannot obtain the proteins for all the various animals, therefore, should these measures fail, the best thing to do is to have the child brought to a hospital and removed from the environment of all sources of animal or flower emanations. This will very often clear up the case and confirm the diagnosis.

The next step is to find the cause by a process of elimination. It is well to remember that contact with the offending material, even for a few minutes, will bring about an attack several hours afterward. Dr. Pisek reported a case in which the patient was sensitized to chicken feathers and when placed upon a cotton pillow was asthma free. The child had another mild attack afterward, traced to a pillow fight the previous evening. Should all these precautions fail to discover the real cause, we can reasonably assume that we are dealing with a bacterial type. All obvious foci of infection, such as caries and infected tonsils, should

be removed. Results are obtained occasionally by this alone. By skin tests it is sometimes possible to isolate the offending organism, in which case a stock vaccine given in gradually increasing doses is administered. Of more value is a culture from the nasopharynx, grown on both agar and bouillon, and a mixture from these used as a vaccine. Some authors advise growing the predominant organism only, but unless this happens to be the one giving the positive skin reaction, I do not believe it is necessary. In case of failure, and as a last resort, either a second vaccine from the nasopharynx or a vaccine grown from the feces may be tried. In the case of pollens, according to the season of the year, and by means of the skin tests, we are also able to isolate the plant for susceptible individuals. These are the only patients who are benefited by changes of climate, sea trips, or seaside resorts with predominating sea breezes.

In the case of food anaphylaxis, it often happens that the patient is sensitized to some widely distributed article of diet, milk for instance, lactalbumen being the most common offender. This can be eliminated by boiling the milk and allowing it to cool, the lactalbumen rising to the surface as thick skin which can be removed. Unfortunately a great many children object to the taste of boiled milk, but it can at least be used for the cooking of their food. Occasionally we have found that dry milk was tolerated in these cases. Yolk of egg rarely brings about any anaphylactic disturbance, while the white is a frequent cause of asthma. Clinical experience has shown that the cereals, when toasted, are less likely to cause anaphylactic changes and can be taken with less harm in this way.

From the most common foods, we can desensitize the patients with small increasing doses of the protein hypodermically. Such preparations are put up in commercial laboratories, as are also a few of the animal emanations and pollens. With such simple food as white of egg we can desensitize the individual by giving a very dilute solution by mouth three times a day and increasing the dose by a minim each time until tolerance is obtained.

During acute attacks, dietary in origin, removing the offending substance by stomach lavage will sometimes afford relief. As time goes on the treatment will probably be considerably simplified, but at present it is chiefly a question of making the patient understand what may cause an attack and when possible, desensitize.

Puncture of the Superior Longitudinal Sinus.
—M. Gonzalez-Alvarez and J. Gonzalez Edo (*La Medicina Ibero*, April 10, 1920) find that this route is one of great advantage in taking Wassermann specimens, in giving quinine solutions in malaria, neosalvarsan in lues, serum in diphtheria, and tetanus; in administering alkalies in acidosis, and for the transfusion of blood. There is only one contraindication, namely, hemophilic diathesis.

THE TREATMENT OF ASTHMA WITH BENZYL BENZOATE BY INJECTION.

BY BENJAMIN WOLOSHIN, M. D.,

New York,

Instructor in Medicine, New York Post-Graduate School and Hospital.

Among the unsatisfactory and at times troublesome patients are the asthmatics. In the clinic, as well as in private practice, one is often confronted by the obstinate asthmatic who, in spite of every mode of treatment, obtains little or no relief. As is the case with all diseases, the etiology of which is not known or definitely established, one frequently comes across reports by different observers, who assert that successful results have been obtained with various methods of treatment. Strange as it may seem, those same methods applied to our patients often result in failure.

While a good deal has been written lately about the use of benzyl benzoate in cases of true asthma, very little is said about its use by injection in that condition. This point is of particular importance when one finds, as we have, that this drug will give gratifying results by the hypodermic route, where oral administration fails. The following case will serve as an illustration.

CASE.—Mrs. L., fifty-four years of age, came under my observation about one year ago, with a history of bronchial asthma of fourteen years' standing, during which time she was under fairly constant medical treatment. Her attacks, which varied in severity and frequency, were as a rule promptly relieved by injections of morphine and atropine or adrenalin. About eight months ago her asthmatic attacks increased in both frequency and severity. Adrenalin would no longer give her relief, while the dose of morphine had to be increased. She was put on benzyl benzoate in twenty drop doses every four hours by mouth. She was completely relieved in several days and remained so for two months. Without any apparent cause she suddenly began to suffer severely, being in an almost constant state of dyspnea. Neither adrenalin by injection nor benzyl benzoate by mouth gave her the slightest relief. The hypodermic administration of morphine, one third to one half a grain every four to six hours, was necessary to give her temporary alleviation. This condition continued for about two weeks. She became obstinately constipated, took scarcely any nourishment, her skin was dry, tongue parched, heart action poor, pulse rapid and weak, thus presenting a picture of misery. I put her on benzyl benzoate, twenty drops every three hours by hypodermic injections, and digalen, ten drops every four hours by the same method, at the same time cleansing her alimentary tract with salines and colonic irrigations. In three days she was completely relieved, was out of bed at the end of a week, and has been free from attacks since.

I believe we are justified in emphasizing here the value of digitalis in asthma, particularly in cases of long standing, where the resulting dilated right heart, with the consequent impaired pulmonary circulation, adds greatly to the sufferer's embarrassment.

1331 PROSPECT AVENUE.

EXAMINATION OF THE EYE ESSENTIAL IN PHYSICAL EXAMINATION.

BY J. A. KEARNEY, M. D.,

New York,

Professor of Ophthalmology New York Polyclinic Medical School and Hospital. Ophthalmic Surgeon Out Patient Department Gouverneur Hospital, Ophthalmologist Out Patient Department, French Hospital.

Today the fashion of endeavoring to trace general constitutional disturbances to foci of infection and to toxemias of various origins is prevalent and records show strikingly important results from this wave. The imbalance of interaction of the endocrines also occupies a prominent place at present. Enthusiasts in these important studies sometimes neglect other time honored determinations, the treatment of which, when found, has given relief repeatedly.

The necessity of examining the eyes is seldom disregarded nowadays, when headaches and eye discomfort and pain exist, but symptoms that occur remotely from the eyes are often overlooked as being the probable result of existing eye affection or undue ocular strain. Indigestion, flatulent and other dyspepsias, malaise, insomnia, as well as headaches of various characters, not infrequently disappear when a dry and roughened conjunctiva is cleared up by treatment or when correcting glasses for existing errors of refraction and imbalance of extrinsic ocular muscles are worn for a time.

Valuable information may be elicited from a complete ophthalmoscopic examination of the fundus of the eye that cannot be obtained in any other way. When certain changes from the normal are observed, they are often leading indicators of some general or special malady that is now present or has existed heretofore.

Retinal hyperemia, hemorrhages, fatty degeneration and atrophy or combinations of two or more of these, which may be observed in the eyes of patients with nephritis at times, aid in determining an existing kidney affection. Indeed the so-called typical albuminuric retinitis in which fatty degeneration and atrophic changes occur about the macula (macular star) is not as frequently observed as the less elaborately produced lesions of this affection. The recorded proportion of retinitis in nephritics varies from nine to thirty-three per cent. and it would be considerably higher if there were included the minor blurrings of the disc and retinal details, the result of slight alterations in the walls of the blood vessels and the reaction in the retinal tissue to cytotoxic substances in the circulating blood. In diabetes, similar changes are noted in the fundus that occur in nephritics, but retinal fatty degenerations and atrophies occur in the equatorial regions more frequently than about the macula as in albuminuric retinitis. When retinal degenerative changes are noted in diabetes the disease is usually advanced and prognosis as to life is grave, just as similar changes in the retina of patients with nephritis denote a bad prognosis. Cataracts are not uncommon concomitants of diabetes.

In a recent attack of syphilis an eye ground examination is expressly required by leading syphlographers, particularly when intravenous medication with arsenical preparations is to be employed, as certain diseased conditions when found in the eye fundi may contraindicate its administration or compel modification of its use. Later in life when other untoward general conditions develop you will discover, on taking a previous history, that a luetic infection is frequently denied or forgotten or it may have been innocently contracted, and the early evidences may have disappeared without any medication. If scars, atrophies or old exudates are seen in the fundus oculi as the result of the early stages of this disease, a doubtful tertiary aspect may be cleared up years after the occurrence of the initial infection.

Arteriosclerosis may be observed as a kinking and tortuosity of the smaller retinal blood vessels in the earliest stages, and in the later stages by an indent noted in a vein where an artery crosses it. When these changes are noted, similar vascular conditions may well be suspected in the cerebral blood vessels. If twenty-four hour interval observations of the fundi of the eyes are made in all cases of apparent or suspected recent fracture of the skull, sufficient edematous changes may frequently be noted which will suggest a possible intracranial pressure. This is often verified by lumbar puncture. A cranial decompression operation in these cases removing a cerebral blood clot or just relieving the pressure, is reported to have saved many lives.

The location of basal brain injuries, softenings and hemorrhages, occurring in the pathways of the visual fibres from the back part of the eyeball to the perceptive centres of vision in the occipital lobes of the brain, may be traced when existing hemianopsias or even less marked amaurotic areas occur in the retinae, together with a notation of pupillary activities, when light is thrown upon the retina of one or both eyes. A fundus examination has at times revealed a choked disc, the result of a brain tumor, in patients admitted to our hospitals suffering from persistent uncontrollable headaches and said to have an obscure neurological condition.

A neurological examination that includes the following data derived from an eye examination is always more valuable than one that does not: The diameters of each pupil, their shape, the difference in their size, their reactions to stated stimuli, the state of health of the extrinsic ocular muscles, the refraction error, if one exists, the degenerative edematous, inflammatory and other untoward changes in the optic nerve head and retina, if any are present, the variations in the structure of the retinal blood vessels, amaurotic areas in the retina, visual acuity and visual fields for form and colors.

A doubt as to the diagnosis of meningitis is often cleared up by characteristic changes that may be seen at the time in the fundi of the eyes as the result of this disease. Migraine symptoms are sometimes relieved by wearing accurate correcting lenses when a refraction error or extrinsic ocular muscle imbalance is found to exist and occasionally a cupping of the optic discs is discovered in a fundi

examination denoting a glaucomatous process that may be the source of the symptoms. Tonometric and other examinations usually verify the diagnosis by recording an increase in the intraocular tension.

Monocular papilledema suggests pressure extending to the optic nerve from diseased adjoining nasal accessory sinuses, particularly the frontal ethmoidal and sphenoidal. Toxemias lasting for a time tend to disturb the subretinal pigment layer and cause particles of its pigment to migrate into the retinal tissues proper, changing the color of the retina, from that corresponding to the complexion of the patient and in some instances giving the eye ground throughout a pepper shaken appearance.

The general conditions cited in this paper are ones most commonly met and for this reason they are reviewed with some of the accompanying eye changes to show the importance of an eye examination in all thoroughly studied cases.

SUPPLEMENTAL ACTION IN REPARATIVE MEASURES.

With Special Reference to Serogenic Remedies Reinforced Through Kinotogenic Agencies.

By J. MADISON TAYLOR, A. B., M. D.,
Philadelphia,

Professor of Physical Therapeutics and Dietetics, Medical Department, Temple University.

Evidence is accumulating to the effect that groups of efficient therapeutic procedures mutually supplement each other, hence results can be obtained in proportion to the resources of each being understood and judiciously applied. Of the four major groups, a, medicines, b, serums and vaccines, c, mental readjustments and, d, so-called physical remedies, the last have not yet come to be accredited the importance they deserve, nor are the established principles adequately understood or appreciated. All clinical problems, except the simplest, need to be approached from most, if not all, of the directions indicated.

Let me here offer further evidence of interaction between the two groups, the serogenic and the kinetogenic or the physical, or mechanical. Also permit me to suggest a descriptive name for this last group of agencies which seems best calculated to convey an exact meaning, and that is kinetogenic instrumentalities, since they all involve motivation in some of their diverse modalities. Among these are electricity (electrogenics), heat and cold (thermogenics), light (photogenics), the adjustments of the mind or emotions (psychogenics), and orthogenics, physical or morphological adjustments of the body, the muscles, joints, reflexes, etc., through movements on or by these structures, i. e., passive or active.

Another point offers, namely: Any remedial agency induces effects in a twofold manner, yet in varying degrees, by a, influencing the organism as a whole, and b, upon areas or localities or groups of structures. It seems to be assumed by many that the effects of most medicaments or serums or vaccines are so widely diffused that their influence is exerted

uniformly upon the organism as a whole. The fact is, or many facts are becoming adduced to prove, that we have much to learn of these varying local states wherein energies in their transmission are often delayed, retarded or accelerated or otherwise unequally distributed. In respect to the sera and the problems of immunity, Sir Almroth E. Wright has told us much, especially in his recent communications.

The central aim of all therapeutics may be described as the achievement of cellular poise, the equalization of blood and lymph propulsion leading to wider distribution of vital fluids, principles, hormones, antibodies, adrenoxidioxidase and other essentials to life processes, also the reduction of end products to conditions favorable for elimination. The instrumentalities include hydrostatic, hematogenic, thermogenic, and the profoundly complex reflexogenic mechanisms. Likewise there are now coming to our attention electrotonic factors which may prove to be of yet deeper significance. The great regulative agencies, the ductless glands, exert influences throughout which must at all stages be reckoned with.

During the processes of functional fulfillment, many associated or collateral factors combine to bring about and maintain a stabilization. The problems thus stretch out beyond our present ken. However, much improvement in therapeutic efficiency will result from achieving a practical familiarity with those forces of which enough is already known.

Among the chief enterprises is the equalization of the reflexes. In particular there may be mentioned the graphic phenomena of, 1, tonicity in the cardiovascular renal mechanisms; 2, resistance in the blood stream and the defence of the organism against interferences with blood flow; 3, tonicity in the various tubular and hollow viscera, the digestive, the respiratory, the reproductive, the genitourinary and other cycles and groups of structures; 4, the extreme significance of balanced tonicity (isotonicity) in the muscles, not alone the large muscles but the small ones as well, as forming parts of, and distributed among these viscera, which is of equal importance, as I have tried to show elsewhere. In short, health consists of maintaining poise in the neuromuscular cycle, especially the release of tonic spasm, cramp, or in the correction of undue relaxation. This attribute of quantivalence it is the prerogative of the mechanisms of movement or rest (kinetogenic instrumentalities) to bring about most promptly and permanently.

An organism would obviously be in a position of far greater advantage to profit by any remedy introduced into the circulation, if measures were available whereby these varied processes could be made to cooperate harmoniously.

Only when the reflexogenic, the neuromuscular and the thermogenic mechanisms, in short equalized tonicity, temperature and propulsion are, and remain at their norm, or so near their norm as to functionate economically, is it possible for the subsidiary, collateral or finer mechanisms to perform their functions to advantage. Only when the structures of an organism exhibit fair tone, uni-

formity of pressure, hydrostatic and osmotic competency, temperature, automatic selfregulation of those forces essential to distribution of nerve impulse, also static or kinetic support, can balanced interaction be attained and maintained. Only while an organism is, and continues to be, in such a state of harmonious integration can it be expected that nutrient fluids and cells can be sent where or when they are most needed, or can any curative substances, principles, enzymes, sera, and the like, be distributed promptly and do perfect work.

Such helpful agencies are available and efficient. At least it is necessary to concede the efficacy of these accessory or supplemental, indeed these essential instrumentalities, and to give to them the same critical study, also to grant them the same confidence when demonstrated or proven, as is now so freely accorded to pharmacodynamic agencies. Consider, in this connection, the significance of the biological law that protoplasm tends persistently and unerringly (unless thwarted by excess stimulation) to come back to the original state as soon as the stimulus ceases.

This reaction to stimulation can be secured almost indefinitely, short of exhausting the governing reflex or reflexes, or the controlling centres. Also it obtains that no destruction of cells follows upon a mechanical stimulus, whereas, on the contrary, after stimulation by a chemical agency there invariably follows more or less change in the cells or fluids or structures. Whether sera, vaccines or other bacteriogenic agencies produce chemical or mechanical changes I do not know. These substances come close to being foods. Thus the supplemental power, perhaps superiority of kinetogenic agencies, modalities of motion, or mechanical stimuli to function are made clear. At least they are wholly safe.

The point to be determined by research in this domain is: How far can present biokinetic measures be relied on and how far can they yet come to be developed? Meanwhile the pertinent query is: How far can the effects of serogenic remedies be influenced, expedited or enhanced through biokinetic instrumentalities?

Obviously their distribution can be materially expedited and hence their effects amplified, at least through enhanced solution, absorption and distribution, thus inviting antibodies to remote parts when materials are introduced into the blood currents.

Let me cite here and later from Sir Almroth E. Wright's address (2): "Therapeutic inoculation can be approached also from a point of view different from that taken up by Pasteur. With respect to immunizing response, the body has been visualized as a single and undivided unit. That is clearly erroneous. One region of the body may be making immunizing response while the other is inactive. For instance, in the stage of incubation it is presumably only the region which is actually harboring the microbe and in the stage of generalized infection it is presumably the entire body which is incited to respond. And again, in localized infections we may—making here some reserves—assume that we have only localized response.

THE DEFENSIVE MECHANISM OF THE BODY.

"To combat bacterial infection the organism must have defensive powers. That power of guarding itself against infection we may call phylactic power. The leucocytes and the bacteriotropic substances in the blood fluids we may call phylactic agents. There is required also efficient staff work to bring your defensive force to the point attacked. The self same thing applies to the body. You must have not only phylactic power in the blood, but also provision for the transport of your leucocytes and bacteriotropic blood fluids to the site of infection. Let me call this transport of phylactic agents to the site of infection, kataphylaxis. Let me term any condition which interferes with that transport an antikataphylactic influence.

"When in sound physiological condition, we have efficient kataphylactic arrangements—blood fluid and leucocytes have unrestricted access to every portion of the body. But when antikataphylactic influences are brought to bear; when the arterial supply is uninterrupted or is closed down by collapse, or the body is petrified by cold, and the alkalinity of the lymph is blunted off by acid metabolites derived from the muscles; then the emigration of leucocytes is arrested, and the transport of blood fluids into the tissues comes to a standstill.

ECPHYLAXIS.

"I drew attention twenty years ago to the terms 'regions of diminished bacteriotropic pressure,' 'non-bacteriotropic niduses,' and nonbacteriotropic envelopes.' These terms have not proved effective missionaries of the idea, and I would propose now to try to put into currency instead the terms ephyllaxis, ephyllactic region and ephyllactic envelope. When I speak of an ephyllactic region you will understand me to mean a region in which the guardian elements of the blood have been rendered impotent or, as the case may be, have been excluded. In describing the effects produced by the abolition or suspension of the circulation by injury to the blood vessels or exposure to cold, I was picturing to you an ephyllactic region. Much more commonly the ephyllactic region has been fabricated by a bacterial colony. You will appreciate that every living bacterial colony must become the centre of an ephyllactic sphere. It will become so, a, by radiating out toxins which will (when of sufficient strength) repel leucocytes; b, by absorbing bacteriotropic substances from the blood fluids; and probably, c, by abstracting antitryptic power from the blood fluids and so converting these into a congenial culture medium."

HOW CAN WE PROFITABLY CONTROL BLOOD PRESSURE AND LYMPH PROPULSION?

As supplemental measures for enhancing the effects of bacteriotropic or serotropic or pharmacotropic remedies, we may mention: Thermogenic, various modalities of heat and cold, the balancing of temperature conditions whereby various expeditive or retardative effects are wrought on cellular activities, on phylaxis, kataphylaxis, antiphylaxis, also ephyllaxis, apophylaxis and ephyllaxis.

As Wright says the kataphylactic measures include evacuation of an ephyllactic focus; also nor-

mal conditions may be restored by augmentation of the transudation of lymph into the focus of infection and displacing and expelling by this agency the ephyllactic lymph; also by restoring physiological conditions by processes of diffusion. Let me quote Wright's recommendations:

KATAPHYLACTIC MEASURES.

"Normal conditions may be restored by augmenting the transudation of lymph into the focus of infection, and displacing and expelling by this agency the ephyllactic lymph. Physiological conditions may be restored by processes of single diffusion.

"1. *Procedures for evacuating the ephyllactic fluid into the exterior.*

a. Incision into the focus of infection.

b. Incision and cupping. In actual practice the method fails, when, as in carbuncle, we have to deal with lymph spaces blocked with leucocytes and coagulated exudate.

c. Application of hypertonic salt solution to naked tissue surfaces.

d. Application of irritant solutions to naked tissue surfaces. An outpouring of lymph.

"2. *Procedures for restoring normal conditions by augmenting transudation from the blood and displacing and driving out the ephyllactic fluid from the focus of infection.*

"Under this heading may be enumerated three procedures: the application of hot fomentations, the application of a Bier's bandage, and massage. In the first two we make use of increased transudation—obtaining that increased transudation in the one case by active and in the other by passive congestion. In massage we use mechanical propulsion. It will generally be inapplicable to an active focus of infection.

"3. *Procedures for restoring physiological conditions in the focus of infection by spontaneous diffusion of protective substances from the blood.*

"If we had under Socratic cross examination the man who expects benefit indiscriminately from every therapeutic inoculation it would be elicited that he had a confused expectation that the protective substance obtained by inoculation would diffuse into, and do effective work in, every focus of infection. In the case of a focus which has attained a certain magnitude that cannot by any possibility happen, for the infecting microbes are incessantly obstructing the work of immunization. They are continuously paralyzing and repelling the leucocytes and depraving the blood fluid to their advantage, and thus they neutralize and more than neutralize the instreaming protective substances. We get as good as no success from therapeutic inoculations when dealing with large and unopened foci of infection; and our very best when as in prophylactic inoculation, we are dealing with infecting microbes before they have had time to fabricate round themselves an ephyllactic focus.

"Of such dominating importance is efficient kataphylaxis in the conflict with bacterial disease that I do not hesitate to assert—and these are views with which every surgeon will fall in—that if we were to put our election, on the one hand, between efficient

epiphylaxis without kataphylaxis; and, on the other hand, efficient kataphylaxis without epiphylaxis, we ought every time to choose the latter."

In a paper read before the American Clinical and Climatological Association (3) I reviewed the subject carefully.

Let me here remark upon the topic of massage or better manipulative procedures in this connection. The profession has by no means directed its attention adequately to the resources of manipulation. Ancient error, prejudices and queer preferential limitations still prevail. What are the contraindications to massage which are still believed to obtain?

Among the more unfortunate dicta which demand revision are: 1, Not to apply massage to a patient in whom fever is present. On the contrary this is often most necessary, since by gentle strokes, light touches, as Menell has shown, extraordinary results can often be obtained in relaxing local or general vasomotor overtension.

2, To avoid massage in the vicinity of wounds, devitalized, injured or infected areas, structures, etc., also where diseases of the skin exist, such as eczema. The fact is that the application of massage to contiguous areas is often followed by prompt repair, cure or pronounced advantage.

3. To avoid massage where the heat making (thermogenic) mechanisms are overborne. Here it is demonstrated that massage affords one of the most efficacious means of restoration. This effect of restoring equipoise in the heat generating mechanisms is peculiarly valuable, notably in conditions of lymph stasis, when subdermal adhesions are present, and the like.

REPUTABLE INFERENCES.

The evidence in behalf of the efficacy of kinetogenic instrumentalities as contrasted with pharmacogenic and to meet diversified emergencies is steadily growing. It demands openminded attention and confidence. Heretofore serogenic remedies when applied have been relied on to suffice alone. Now evidence is accumulating to the effect that these can also be enhanced by—may indeed often demand supplementing by—the kinetogenic. By common consent of surgeons who have actually worked under Willems in Belgium, he has made the largest contribution to surgery of the war in his method of treating acute septic arthritis and traumatic arthritis by compelling volitional effort from the start.

I may cite a personal communication to Dr. S. Fosdick Jones, of Denver, Col., who worked under Willems to this effect. So also of the work of Dr. La Panne at the *Ambulance de L'Ocean*, in preserving function in amputations. Further clinical evidence is needed but here we have indicated most promising accessory measures.

HOW TO PROTECT THE HEALTH OF SCHOOL CHILDREN*

By IRA S. WILE, M. D.,
New York.

While foreign nations are grappling with the problem of repopulation, the United States is busily concerned with the questions involved in conserving the existing generation and in improving the chances of survival of those still unborn. Public health measures of the past decade have shown a material advance in the direction of efforts to protect the health of school children. In the evolution of this work, more attention has been bestowed upon children during the school age than at any other period of child life, save infancy.

As a matter of logic, devoting attention to children during the school age represents merely an entering wedge into work with children. Because of the glaring handicaps and defects noted in the school population, rationally, the protection of health during the school period should be begun before entrance upon school work. In other words, the potential school child presents a more important problem for public health work and, in consequence, every effort should be made to supervise, control and impart the necessary hygienic information concerning childhood during the first six years of life. Any system of public health may be said to be caring for children inadequately, unless its efforts are directed along lines of prenatal work, the organization of infant welfare stations and the continuous care of children during the preschool age.

For this reason I emphasize the necessity of guiding childlife from conception to the age of six years, as a prerequisite or rather a fundamental part of hygienic protection of the school child.

The purpose of education is thwarted or handicapped when the pupil is physically or mentally incapacitated to receive an education or indeed to develop its latent potentialities. The reports of medical inspectors, indicating the numerous defects and handicaps of school children, bear witness to our failure properly to prepare children for the educational system. The recognition of defective nutrition, carious teeth, impaired vision and hearing, spinal curvatures, pathologically enlarged tonsils and adenoids certainly merits attention during the preschool period. The postponement of attention to handicaps of this type until school work has been begun is indicative of a failure to appreciate the necessity for entering children into school work, capable of functioning in as nearly a normal manner as is humanly possible in the present state of our knowledge.

Economically and socially it is distinctly advantageous to spread some of the attention now bestowed upon the school epoch over the period of life antedating the school age. It is simpler and cheaper to undertake protective measures at the time suggested than to wait until there are additional charges to the community through wastage due to the loss of time, because of preventable diseases or corrective measures.

* Read before the Child Health Conference at Asbury Park, N. J., June 12, 1920.

The protection of the health of school children must take cognizance of more factors than are ordinarily considered. The physical bases of health have received considerable attention but insufficient thought has been devoted to the matter of educational, social and moral factors involved in the health of school children. Our sphere of influence must be enlarged in conformity with the concept of the unity of childhood and the interrelations and interdependence of all factors affecting health. No longer is public health work restricted to the consideration of contagious diseases and personal handicaps. It now contemplates the broader horizon of health, as covering mental and moral wellbeing, and thus influences methods of administrative procedure.

From the more traditional point of view, conserving the health of school children involves the recognition and correction of the existent defects and handicaps and the establishment of methods tending to prevent the development of such obstacles to normal development during the school period. Obviously, if a large part of this work is performed before entrance into school, there will be less of the corrective work to be done during the school period. The need would still exist for the complete examination of new pupils along present lines with a view to determining their physical status and improving upon it.

The regular procedure involved in medical inspection for the prevention of contagion and the control of children during the existence of epidemics is of inestimable importance. The mere tabulation of statistics, however, is without service to the state, save in so far as it indicates the problems to be attacked. Correction of defects is the only excuse for efforts at detection.

Every system of medical inspection requires for complete usefulness a followup system which will insure a full measure of attention for every child found to be physically handicapped. In this connection, of course, the school nurse is a necessity, while a great deal could also be accomplished through the home and school visitor, discussions before mothers' clubs with voluntary committees, willing and able to assist the medical inspectors in carrying out their program.

The importance of dental disorders has now been recognized so that an inclusive health program merits the assistance of dental hygienists and dentists. This phase of dental hygiene, though fully appreciated for several years, has not received the attention it deserves. The haphazard service given the mouths of children during the preschool age has deluged the schools with children whose dental state is lamentable.

I am firmly convinced that in the expansion of state oversight of school children, more use will be made of school clinics, which will serve as the rallying point for health centres, now growing in favor. These school clinics may merely serve as clearing houses or under careful management may offer adequate instruction to care for a large proportion of the conditions requiring continuous direction and control. This is particularly true of health classes which are established for the purpose of

alleviating malnutrition, postural defects, unclean mouths, etc. I believe also that more attention is required to the physical welfare of teachers. The means to be employed must necessarily vary according to the regulations for admission to the educational system, and in consequence I hesitate to suggest a definite program, though the reason for one is apparent.

The problems of physical sanitation, involving light, heat, ventilation, adjustable furniture, the use of water, towels and toilets, are sufficiently important to be given consideration in any large plan involving the complete protection of the health of school children. In addition to these questions, largely taken care of by departments of education, there offers a broader educational field which is of interest from the viewpoint of public health. I refer specifically to the need for special classes for cripples, the blind and the deaf, as well as provision for open air classes for children, anemic, or convalescing from intermittent diseases and children in the pretuberculous or incipient tuberculous stage. Furthermore, there is a necessity for classes aiming to conserve vision, particularly for myopics, and likewise the institution of methods for the prevention and the correction of speech defects. All of these classes while ordinarily regarded as parts in an educational system, in the same way as are the ungraded classes, by reason of the conditions calling for their existence, are also classes possessing a value protective to the health of school children.

They are designed not merely to give special attention to the education of handicapped children, but to do so without sacrifice of greater vitality and indeed with a desire to supplement and increase their latent physical powers and development. From the health viewpoint, as well as the social point of view, the serving of school lunches must not be forgotten, though the underlying basis of this need is found in the ignorance of dietetic requirements, slightly complicated by inadequate family incomes.

It is unnecessary to dwell upon the interrelation of physical and mental causes in the health of school children. The aim of public health work with children is not merely in the value of physical health to the individual, but lies in the worth of efficient citizenship. Patently, this involves mental health as well as physical wellbeing. For this reason the mental health of the school child merits protection. The amount of interest which has been manifested in children of low mentality should be given the entire school population. Those children whose social and economic returns to the state will be of greatest value deserve as high a degree of mental protection as those whose greatest return will be a low limit of self support or those who possibly will require institutional segregation. Under a rational system, every child in school would receive a psychological test with the determination of its intelligence quotient as one of the factors in determining its school adjustment. The child capable of doing work of the third year should not be obliged to mark time in the first year class, because it is chronologically six years of age, and thus begin the formation of habits and conduct

harmful to its mental development. The growth of the mental hygiene movement bears witness to the importance of undertaking some new program in connection with children of the school age. There is a great need for proper school adjustments, the development of rapid advancement classes, and the giving of thought to the bright children just as is now given to morons and imbeciles. Pedagogical discrimination forms an important part of mental hygiene, but the urging of health authorities would be useful in hastening the advance of the educational aids in promoting mental health.

Nature has been kind to children in that it has provided certain natural barriers preventing over study and overwork in school. Nevertheless, there is a growing demand for greater elasticity in school curricula, a longer school year, promotion by subject, and a more careful distribution of work, study and play in school life. I mention these phases of educational work, because health departments and bureaus of child hygiene can find a greater field for the expression of opinions concerning the improvement of health and for giving wise counsel to school children through a higher degree of cooperation with educational systems. It seems irrational to establish clinics of mental hygiene, without at the same time entering upon a campaign to safeguard growing generations against mental disabilities due to faulty school methods.

From the same point of view, the protection of school children involves more knowledge concerning the hygiene of teaching, the proper adjustment of school hours, particularly during the first few years, the balance of recreation, the advantages, methods and dangers of physical education. Many groups of children suffering from such handicaps as cardiac diseases, tuberculosis, crippling, flat feet, deformities of the spine and similar conditions demand the adjustment of school program, and this should be a concern of health authorities.

It must be obvious that no scheme of protecting the health of school children would be complete without at least mentioning the importance of teaching hygiene in its widest implications, not merely as an isolated subject, but as part of every subject with which it has correlation. The institution of events in educational circles under the stimulus of health departments, such as Babies' Week, Clean Up Week, No Accident Week, Health Day, etc., possesses a value from the topical viewpoint but does not suffice to fix the facts of hygiene as firmly as does the proper daily instruction of hygiene in connection with history, civics, geography, nature study, physical education, and indeed English and art, domestic science and manual training. The educational machinery which has revolutionized public health work for childhood, should possess an adequate place in the schools that there may be understanding of the human body in its relations to individual, family and civic health.

One more phase of our general scheme must be considered. The moral factors of health require more attention than the past has offered. The great truths and the underlying purpose of sex education must be imparted to children naturally and rationally, utilizing the home, the school,

the Sunday school, the clinic and the class room as occasion arises. The vast importance of mal-adjustments of conduct and behavior, and the complexes that distort personalities are not to be overlooked, in a complete organization of activities to protect the health of school children. This is merely a suggestion, because it would involve too long a period of time to give it adequate discussion.

I have endeavored to present briefly, though it may not appear so, my conception of the field of work that must be entered in order to give due consideration to the important elements entering into the health of school children. Laying greatest emphasis upon the organization of health work during the prenatal period, infancy and the pre-school age, I should continue every line of endeavor thus begun, permitting them to expand in the directions that child nature develops. The physical, mental and moral phases of child health require guidance, support, constructive suggestion and remedial efforts. These indicate a large variety of functions to be consolidated and coordinated. On this broad principle I believe it will be possible to build up a type of work that will lead to a complete system of health protection for school children. With such a plan and an adequate organization the future will find the nation richer in man power and woman power and with a greater confidence in the healthful development of the future generations.

BACKACHE FROM THE VIEWPOINT OF THE GENERAL SURGEON.*

BY MOSES BEHREND, M. D.,
Philadelphia.

In a symposium of this character the general surgeon has to some extent an advantage over the gynecologist, the orthopedist, and the urologist, provided he received his training before the various branches of surgery were specialized as they are now. Theoretically, we can divide the back into the gynecological, the orthopedic, the neurological, the medical, and the surgical back. The surgical back refers especially to injuries which may result in a fracture of one or more spinal vertebræ and to injuries in the loin space, especially the kidneys. Injuries to the body of the vertebræ are the most difficult to treat and at the same time often the most benign. Fractures of the spine as a result of a crushing injury may disintegrate the cord to such an extent as to cause permanent paralysis or death in a comparatively short time. Backache resulting from these injuries varies to a great degree. It persists in some cases for a lifetime, especially when the injury has not been severe. There is another type of case in which the patient recovers after a favorable settlement has been made, either in court or out.

Injuries to the back may also occasionally cause traumatic inguinal hernia. I have seen two such cases resulting from severe blows on the back, the

*Read at a meeting of the Northern Medical Association of Philadelphia, May 14, 1920, as part of a symposium on backache.

hernia being of a direct inguinal variety. The patient operated upon most recently gave a history of having received a blow on the back while lifting a case of glass from a wagon. There was no history of a previous hernia and at operation there was no preformed sac. The patient was brought into the hospital with the hernia irreducible immediately after the accident. It is well known that a large hernia often causes backache on account of the attachment of the mesentery to the spinal column. The dragging of a large scrotal or vulvar hernia would necessarily give rise to some discomfort in the back, especially if adhesions were present, and very often this was the case in old irreducible hernias.

The appendix must not be forgotten in considering a subject so important as backache. We all know that an acutely inflamed appendix often gives rise to pain in the loin space, especially where the appendix is posterior to the cecum and pointing in the direction of the gallbladder. The character of incision will often depend on the diagnosis of an appendix in this position. In chronic cases, where the appendix is tightly bound down to the cecum and the peritoneum, backache is often a symptom of this condition. Only recently a patient was admitted to the hospital in whom we diagnosed right tuboovarian disease and retroversion. On opening the abdomen the pelvic organs were found to be practically normal but a chronic appendicitis existed in which the tip of the appendix pointed in the direction of the gallbladder.

At times grave disease in the loin space, such as retroperitoneal sarcoma may be retroactive, namely, in the early stages of its growth pain may be referred to the anterior portion of the abdomen instead of to the back. This I believe is found only in the early stages of the disease. As an illustration of this point I should like to cite the case of a young boy who had all the symptoms of chronic appendicitis, this diagnosis having been made by a reputable internist and myself. The appendix was removed and the youth left the hospital in a short time. About eight weeks after the operation he complained of backache, for which no assignable cause could be found. A late infection of the wound was thought of but this idea had to be discarded when shortly afterward a swelling was found in the loin space rather high up under the border of the ribs. We operated again on account of the swelling and intense backache and notwithstanding all the well recognized treatments, such as Coley's fluid, radium and the x ray, the boy died complaining persistently of the most intense backache.

Dr. Hirsch has alluded to stones in the kidney as a cause of backache. It is difficult to separate the consideration of gallstone from that of kidney stone. When these symptoms occur on the right side there may exist some doubt as to the proper organ involved but one must bear in mind that colic from stone in the kidney starts in the back and then radiates down the front of the abdomen, while in gallstone disease the pain usually starts in front and then may radiate to the back, even to the shoulders. The character of the pain from these sources may be quite alike, bor-

ing or knifelike in character, or, as one patient described it, as though some one was taking his five fingers and trying to dig a hole through to the back. There may be silent stones in the gallbladder similar to those in the kidney, but when old gallbladder disease is present, with obstruction of the cystic duct, there is often a continuous backache, especially after meals. This symptom accompanies the so-called symptoms of indigestion.

Ulcer of the duodenum and ulcer of the stomach on the anterior wall, the lesser curvature, or at the pylorus, rarely give rise to backache, but ulcers on the posterior wall of the stomach, especially those adherent to the pancreas and even to the parietal peritoneum, may cause backache burning in character. Recently I have operated in several of these the cases of ulcer on the posterior wall of the stomach. The same may be true of cancer of the stomach in its early stages, backache not being a prominent symptom until adhesions occur between the pancreas, the stomach, and other organs.

Syphilis when it affects the liver may give rise to a continual dragging sensation in the back. This refers especially to the massive liver that accompanies some cases of syphilis. To illustrate this point I will cite the case of a patient with a large, soft swelling in the abdomen, who was admitted to the hospital. Many diagnoses were made because the Wassermann reaction was negative. At operation the liver was found to extend from the diaphragm to the os pubis, hiding entirely from view the coils of the intestine. A section of liver was taken for histological study and another Wassermann was obtained because we were not satisfied with the result of the first Wassermann, which was not made in the hospital. The second Wassermann was positive and the histological study confirmed the diagnosis.

1427 NORTH BROAD STREET.

MEDICAL MEN IN THE AMERICAN REVOLUTION.

The New York Campaign of 1776.

BY LOUIS C. DUNCAN, M. D.,

Washington, D. C.,

Lieutenant Colonel, Medical Corps, U. S. Army.

(Continued from page 349)

THE MEMORIAL OF THE REGIMENTAL SURGEONS TO
CONGRESS.

This sets forth that when troops were assembled in haste, at the first breaking out of war, regimental surgeons were appointed to accompany them, provided with medicine chests, from the different parts of the country, where they were raised, at Colonial expense. That when it became a common cause of the whole continent, and provision was made, by Congress, for the care of the sick and wounded of the Army, by the establishment of a general hospital, with a Director General, four surgeons and twenty mates, there was no mention of the regular surgeons and mates, nor any provision made for them, either of medicines, instruments, or other

necessaries; yet they were kept in pay. That, in this situation, it might be presumed the hospital surgeons and mates, appointed to take care of the sick and wounded, were scarcely sufficient to attend so great a number of patients as an unhealthy season, or an active campaign might produce; yet the regimental surgeons and mates, for want of a suitable provision, must in their present situation, be very useless; although they were so much more numerous than the hospital surgeons and mates, and always professed an ardent desire of being properly employed, and of answering the design of their appointment. That not knowing where else to look for relief, they had applied to the director general, who assured them of his inclination to serve them; but having no orders to issue out supplies to them, and it being unusual for regimental surgeons to depend upon the General Hospital for all they wanted, he had advised them to make application of the Commander in Chief, or Congress, for establishing a proper method to obtain supplies, promising to second their applications, with the warmest representations from himself. That it was with his advice, the present memorial was drawn up, to lay before Congress. That he had given them several meetings, and a set of proposals were agreed upon, as regulations, provided they met with the approbation of Congress, which were enclosed for consideration; praying for such relief on the premises, as to the wisdom of Congress should seem meet.

The proposed plans will be found in the appendix to this chapter (4).

In July he also sent Dr. Binney to Philadelphia to procure medicines and instruments. Binney wrote him that no instruments were to be had; that the only instrument makers in the city were employed by Mr. Marshall for the Congress. Dr. Binney at length (August 15th) sent forward such a supply of medicine as he could procure, and they arrived at Newark a short time before the retreat from New York. This was a fortunate accident, for they served the hospital established in Newark about that time.

The Director General forwarded the various documents to Congress, together with a long letter of explanation addressed to Samuel Adams, Esquire, and the rest of the medical committee. He stated their troubles, dwelt on the great shortage of supplies with the regimental surgeons, and implored that he be clothed with authority and definite orders. He also referred to the great distress of the army in Canada and enclosed a plan observed by the British in conducting their general and regimental hospitals. He closed with this request:

(6) I beg instruments may be sent us, particularly amputating; crooked needles and sponges. The enemy are at hand; the campaign is opening; I have done all my limited power will allow. I hope, though late, almost too late, that it is not altogether so, either to receive power, instructions, or means to regulate the affairs of my Dept. I have done my duty in giving the necessary information for what is connected with it, and preparing for the faithful discharge of my trust. I now rest the matter on your determinations, being, with all possible regard,

Gentlemen,

Your most dutiful and obedient servant,

JOHN MORGAN.

Congress was busy with many things then, but Morgan's regulations were mainly approved. The

only letter received from Adams was one of August 5th, in which he said:

I have received several letters from you, which I should sooner have acknowledged, if I could have found leisure. I took however, the necessary steps to have what you requested effected in Congress.

Congress had acted on July 17th (5) and complied with most of Morgan's recommendations; practically all, in fact.

This resolution, or law, was on the whole in accordance with the ideas of Morgan, and very nearly abolished regimental hospitals—in law, but not in fact. They continued as before. It put all surgeons, hospital and regimental, on the same level in so far as rank was concerned. It established a system of property returns, and reports of the sick, as well as of personnel. It displays the usual thoughtlessness with which those in authority direct the preparing of endless papers by those under them. It was the answer to Morgan's proposals, and should have been reasonably satisfactory to him. It was not at all satisfactory to the regimental surgeons, who were required to abandon any real hospitals, and apply elsewhere for all supplies except medicines and instruments. They then renewed, with increased vigor, their efforts to undermine Morgan's standing with the Congress. In this work they were soon joined by the Medical Director of the Flying Camp, Dr. William Shippen. Dr. Morgan then obtained permission to go to Philadelphia and lay the case before Congress. He learned that Congress had purchased a valuable stock of medicines that were in the hands of druggists there. As sales had been made from this stock, and considerable quantities sent southward, he feared it might be dissipated, though it was the best collection of medicines that he had ever seen in the American Army.

While on principle opposed to supplying the regiments, he offered to take a portion and supply chests to the regiments at New York, for one year, as an experiment. He says, "I did not conceive that there would be more than forty or fifty regiments assembled at New York; nor did I suppose that half of them would come destitute of medicines and chirurgical apparatus, when I heard that the Southward (Southern) regiments were supplied by the Continental Druggists. I supplied from forty to fifty regiments with medicine chests by the end of August; besides all the branches of the General Hospital at New York, in the Bowery and neighborhood and on Long Island; which reduced many of our capital articles to an insufficiency for the general hospital for the remaining part of the campaign."

For the purpose of supplying the hospitals and regiments, Congress authorized a continental druggist at Philadelphia, on August 20, and elected to that position Dr. William Smith (6). This continental druggist acted as a medical supply officer.

The Medical Department of the Continental Army at this time was modeled after that of the British Army. It consisted of the general hospital, under the personal direction of the medical director, and regimental hospitals, maintained by the regimental surgeons. The general hospital, at first a single in-

stitution, had necessarily been divided and branches of it instituted, at Fort George, Boston and other places. It was served by hospital surgeons, mates, and hired cooks, nurses, etc. These latter were paid from fifty cents to one dollar—not per day but per month. The general hospital was located in large public buildings when possible; otherwise in churches, warehouses, private homes and barns. The value of the ration due the sick was drawn in money. A principal article of the hospital stores then purchased was rum. Some sort of beds and bedding were furnished, but it was customary to put two men (or more) in one bed. It is not strange that hospital fever (typhus) prevailed.

The entity termed a regimental hospital was no hospital in any definite sense of the word. It was merely a collection of the sick of a regiment, in some house, barn or other building. There were no beds or other facilities. Each man brought his own blanket, which was spread on straw. Each drew the ordinary rations; hard bread, salt beef or pork, and a tot of rum. The British regimental hospitals were little better. Dr. Robert Jackson, acting surgeon's mate of the 71st Regiment (Fraser's Highlanders) says that his regimental hospital at King's Bridge was a turf hut. Jackson was afterward captured at the Cowpens on account of having generously given his horse to Tarleton. Having no dressings for the wounded he took off his own shirt and tore it in strips for that purpose. Whatever may have been the effect of this action on the wounded, it so impressed General Morgan that Jackson was soon sent back to the British Army, without exchange. He was captured a second time at Yorktown. He was one of the first surgeons of the British Army to secure commutation of rations for the sick in regimental hospitals.

This system of regimental and general hospitals obtained in both armies for a hundred years. The functionary known as a surgeon's mate was, in both armies, a warrant officer, not commissioned. Later, in the Continental Army the mates received a status somewhat approximating commissioned rank. Dr. Jackson, while performing the duties of a regimental surgeon's mate, was carried on the muster and payrolls as an ensign, which gave him more nearly the rank of an officer.

The controversy between the Director and the regimental surgeons never ceased. They not only refused to report to him but even had the audacity to seize for regimental hospitals the very houses assigned to him for a general hospital by the State of New York. A sample of Morgan's troubles throws light on the various so-called army hospitals of that time. General Fellows' Massachusetts Brigade was stationed along the North River from Greenwich to Chelsea, to defend that line. Morgan rode out with Quartermaster General Moylan to view the sick and the houses where they were quartered. They found one house so crowded with sick that he remonstrated with the responsible regimental surgeon. He says:

On looking into the rooms, they were found to be filled with sick, and the surgeons who had their care, panting for breath, in the midst of them. It was amidst the sultry heat of summer. In vain I represented to him the danger of engendering a putrid, malignant fever, from

crowding so many sick in confined rooms, in that hot season. He had near a hundred sick in the house. I forbade him then, as I had uniformly prohibited every regimental surgeon, from taking charge of more than thirty or forty sick. I recommended to him to send at least one half of his sick to the general hospital, and remove the greater part of his men into the barn. He disregarded my advice, a putrid fever prevailed, he caught the infection and paid the forfeit of his rashness with his life.

The general orders at this time allowed regimental hospitals, under certain restrictions which were seldom observed. In this case Morgan applied to General Heath, but got no satisfaction. He remonstrated with the colonels commanding, but they refused to compel the regimental surgeons either to report to the Director, or send their sick to the general hospital. The colonel of this particular regiment said that if in his power to prevent it, none of his men should ever be carried to a general hospital. When the Director ordered bed frames made, as fast as forty or fifty were made the regimental surgeons carried them off, some two thousand in all. Such were the difficulties of the hospital surgeons that both Dr. John Warren and Dr. Isaac Foster asked to resign and were only prevented from doing so by Morgan. The particularly aggravating thing in the whole affair was that the regimental surgeons were continually writing to members of Congress: an old complaint, not yet entirely cured.

Lord Howe arrived in the Bay on June 29th with a fleet and eight thousand soldiers. The prospects of the colonists were dismal. The Northern Army, defeated and discouraged, was making its way back to Crown Point by slow and painful degrees, sickness and starvation vying with each other in the work of destruction. In every tent there was a sick or dying man. From thirty to forty were buried each day.

Adjutant General Reed wrote, "Had I known the true picture of affairs, no consideration would have tempted me to have taken an active part in this scene: and this sentiment is universal."

Early in June General Clinton arrived from the South with some eight thousand more men; and on the 12th of August still another fleet arrived, with the first of the Hessians, seven thousand eight hundred; men from Bunswick and Hesse Cassell, for whom King George had bargained to pay thirty-four dollars and fifty cents for every one killed, and to count three wounded as one dead. General De Heister commanded this contingent. The calculation as to wounded may well have been based on the experience of the time.

The combined fleet now consisted of thirty-seven men of war and four hundred transports; with an army of twenty-seven thousand men. This was the largest British force ever concentrated in America. The troops were landed on Staten Island. All were well organized, splendidly equipped, and in every way fit and sufficient to have effected their purpose, had they been ably led.

Washington had on August 8th about seventeen thousand men, of whom part were militia, and three thousand seven hundred were unfit for duty, sick. The urgency of the situation brought in more militia, more new men. Of the whole army not six thou-

sand had been in the army a year. The constant coming and going made discipline impossible. Not a single regiment was properly equipped. There were not enough muskets to go around, and many of them were useless. The cannon were small and poor, and without skilled gunners. Knox, the artillery commander, was but recently from his Boston bookshop. General Sullivan had been a lawyer. Lord Stirling's experience had been limited. Putnam's only tactics were to fight. Greene was the most cautious and skillful of the subordinate commanders, but unfortunately he fell sick of a raging fever a few days before the battle (7). The command fell to Putnam, who had little or no knowledge of the ground, and, it must be confessed, was no general.

On August 22nd the British troops on Staten Island began to cross to Long Island in boats, and by noon fifteen thousand men had landed near where Fort Hamilton now stands, with forty pieces of artillery. The force moved to Flatbush and Flatland. Washington hurried over reinforcements and did his best to inspire them with courage, but it was clear that the morale of the troops was low. A shadow seemed brooding over this new army, now about to undergo its first great pitched battle: for it was outnumbered nearly three to one, by a better army; destined to be completely outgeneraled; and to be sacrificed to no good purpose.

The battle, now more certainly anticipated, induced Dr. Morgan to provide more complete hospital facilities. He went before the New York Convention to appeal for buildings to be used as hospitals for the wounded (8). A certain number of houses were ordered turned over to him, and now, with his surgeons instructed, supplies prepared, and hospitals waiting, he may have felt in some measure prepared for the coming battle.

General Greene had intrenched a strong camp, protected by Wallabout Bay on the left and by Gowanus Bay and a creek running into it, on the right. This line was less than a mile and a half long and was strongly fortified—so much so that the British hesitated to attack it after the battle. It was, however, resolved first to defend the line of wooded hills, some two miles in front of the camp, extending from the narrows eastward toward Jamaica. There were four passes through these hills. Greene planned that all should be guarded, and Washington ordered it; but on the day of battle Bedford Pass was left almost unguarded, and Jamaica Pass, farthest east, was without defense. It has been well said that through the latter Pass "marched the Nemesis which dogs the feet of carelessness."

Lord Stirling with five small regiments held the right of the line, next the water. Sullivan with five regiments held the centre, now Prospect Park, Brooklyn (9). A few regiments remained in the fortified lines. At most five thousand were along the line of hills, facing at least four times as many British and Hessians (10).

In front of these passes, two defended, were twenty thousand of the best soldiers that England could produce, which were as good as any in the world. In front of Lord Stirling was General

Grant with two brigades, one Highland regiment and two companies of New York Royalists. Stirling met them in what is now Greenwood Cemetery, and imagined that he held them in check; but they were only biding their time. In the Flatbush Pass Sullivan was likewise confronted with the eight thousand Hessians under De Heister. De Heister fired some shots, but, like Grant, did not engage heavily—the time had not come.

During the night Clinton and Cornwallis with seventeen regiments and eighteen guns had made a flanking march to the east, crossed the unguarded Jamaica Pass, and then turned westward. By half-past eight the vanguard was at Bedford Four Corners. Here the spell of silence was broken; the bands struck up, the troops burst into cheers; and, pushing on, by nine o'clock the advance columns rested on the junction of the old Flatbush and Jamaica Roads, now the junction of Flatbush and Atlantic Avenues; only a few rods in front of the inner line of the American fortifications. Then it was that the two heavy guns sounded the preconcerted signal for De Heister to press the attack.

De Heister heard it and ordered Donop to carry the Flatbush Pass. The Hessians swept through the woods, followed by the Grenadiers, driving before them the feeble forces of Henshaw's and Johnston's Massachusetts and New Jersey men, with Hand's Pennsylvania Riflemen. Sullivan heard the signal guns, divined their meaning, and started for the fortified lines. A detachment of the British had marched through the Clove Road and reached the rear of Miles's Pennsylvanians; they were soon in full retreat. These various regiments, driven backward to the northern slopes of Prospect Hill, were suddenly confronted by the bayonets of Clinton and Cornwallis. They were thrown backward and forward between fire and bayonet. The greater part found themselves shut between closing jaws of fire. The retreat became a rout, and a massacre. The Hessians gave no quarter. Men who had thrown away their arms were shot down or bayoneted. For two hours the area now enclosed by Atlantic, Flatbush and Clinton Avenues saw this unequal struggle. More than five hundred perished, a few were made prisoners (Sullivan among them); a few escaped.

It was nearly eleven o'clock when Grant heard the second signal, which was his order to attack. He had just been reinforced by two fresh regiments from the fleet. Pushing rapidly forward, Colonel Atlee and his 235 skirmishers were soon killed or made prisoners. Huntington's Connecticut men fared little better. And now, with the frontal attack, the Hessians came streaming in on Stirling's left and Cornwallis came hurrying down from the rear to seize the old Cortelyou house on his only road of escape. The situation was now frightful, but Stirling kept his head. He saw that if he could not hold back Cornwallis his whole command must suffer death or capture. He resolved on a costly sacrifice. Taking three hundred of Colonel Smallwood's Maryland Line, he ordered all the remainder of his troops to retreat across the marsh and creeks of Gowanus Bay to the intrenched lines. The rising tide made this more difficult each minute.

Taking his place at the head of the three hundred, all of them boys, he led them straight at the British, posted in the Cortelyou house with two guns; while the Hessians held the adjoining hills. The terrible fire drove them back. But his men were not yet safe. Again he rallied them and led them on this forlorn hope; this time to the house, where for a moment they held the guns. Again and again this little band was led forward. After the fifth rally there were too few for another charge, but it was not needed. The sacrifice had accomplished its end. Stirling's force had escaped. Two hundred and fifty-six of Smallwood's regiment were killed, wounded or missing. A feeble remnant of the regiment struggled across the creek bearing their tattered colors with them. Stirling, an Englishman, rode away across the hills and surrendered to De Heister. Taken on board the fleet, he found Sullivan already there.

The battle was ended before noon. Five thousand men had been surrounded by four times their number. A thousand were captured. Several hundred were killed. General Howe estimated the American loss at three thousand five hundred. It was not that much, but the army was broken up. His own loss he reported as 367 killed, wounded and missing. This was the most discreditable defeat the Continental Army ever experienced, though the men never fought more bravely. Yet it might have been worse. Had General Howe but given the word, his generals, who were eager, would have rushed on the intrenched lines, almost certainly have carried them, and captured the whole American force on Long Island. The loss, some eight thousand men in all, would have ruined the army.

At the close of the day the intrenched camp was filled with the weary, beaten, and dispirited soldiers. Some were wounded, many without arms; all discouraged. Hundreds of the patriotic farmers of the neighborhood had fled to this place of refuge, driving their flocks and herds with them to prevent their capture. Drenching rains filled the trenches with water and added to the general discomfort. A thousand cattle roamed about the camp. But the vague terrors of the night at length gave place to the more definite apprehensions of another day. A thick mist clung to the landscape, concealing the enemy.

During the afternoon two brigades had been brought over. At four in the morning Washington came to cheer and reinforce his shattered forces. He brought Shea's and Hands's Pennsylvania Regiments, and a little later came Glover's Regiment of Marblehead fishermen. There were now nine thousand men in the intrenchments, and Washington at first resolved to hold them. But when the mists cleared away, revealing twenty thousand men in his front, he resolved to retreat. On the night of the 29th the whole force was withdrawn to Manhattan Island. The Pennsylvania regiments of Hand and Shea were crossed first; the Delaware and Maryland regiments formed the rear guard. Glover's regiment handled the boats, and a heavy fog aided the undertaking.

The regimental surgeons had little opportunity to follow Morgan's teaching in this battle. Several were captured. They may have collected the early

wounded behind the hills; but suddenly this line also was attacked, there was no longer any rear. The army broke up and fled. Those wounded able to walk had some chance to escape; the severely wounded were captured and the majority killed. Brigadier General Woodhull of the militia was killed while a prisoner, by De Lancey or some of his Royal Americans. Some of the wounded, however, escaped. All were removed to New York, by order of General Washington, (11) on August 29th, before the evacuation.

NOTES.

1.—John Warren, younger brother of Joseph Warren, was born in Roxbury in 1753. He graduated at Harvard in 1770, studied medicine with his brother, and began the practice of medicine in Salem in 1772, being but nineteen years of age. He attended the wounded at Bunker Hill, and while trying to reach his brother received a bayonet wound. After the battle he was appointed a hospital surgeon, and served in the hospitals about Boston. He accompanied the army to New York, and was, as we have seen, in charge of the hospital on Long Island. Later, he was at Newark and Philadelphia. At Trenton the army marched in the night for Princeton, leaving the surgeons behind. They galloped off, barely escaping capture. In 1777 Warren was made superintendent of hospitals at Boston, and served there until the end of the war. For forty years Dr. Warren occupied a foremost place among the surgeons of New England. In 1785 he was made professor of anatomy and surgery in the newly established medical school of Harvard. He was first president of the Massachusetts Medical Society, and held that position continuously from 1804 until his death in 1815. His son, John Collins Warren, 1778-1856, was a distinguished medical practitioner, teacher and writer.

INSTRUCTIONS TO JOHN WARREN, ESQ., SURGEON OF
THE GENERAL HOSPITAL, WASHINGTON, D. C.

NEW YORK, June 12, 1770.

Sir:

You are desired to go over to Long Island and to consult with General Greene, about the proper houses for the forming of a hospital (to be part of the general hospital) for the reception of the sick in his brigade. For your assistants you will be pleased to take over three of the hospital mates, of which Mr. Glover is to be one, the other two as you agree with the other surgeons.

Make out a proper assortment of medicines, such a list as you think needful, after consulting with Dr. Foster, Dr. Adams and Dr. McKnight, and order it to be put up from the hospital stores. If you have occasion for further assistants, make requisition from General Greene's brigade, of as many surgeons and mates as you shall stand in need of.

Keep a register of the sick, in which you are to make an entry of the times of their admission and discharge, as well as of the diseases they labor under; and require of the respective surgeons of the different regiments, weekly returns of the sick in the hospital belonging to their regiments; in order to compare with yours: From which a roll is to be made out once a month, for receiving the ration money from the commissary general.

What nurses you require for the sick, you will engage at the price of half a dollar per week: the number not to exceed one for every ten persons sick or wounded; the necessary laborers to be employed by the day, as usual, in which avoid engaging a greater number than is absolutely necessary.

Deliver out no stores of any kind to the regimental surgeons. When the sick require further aids than they can give, let them be reported to you, and if their cases require it, receive them into the general hospital. Take with you at least 1,500 bandages, and a quantity of tow, with a set of capital instruments, and all suitable dressings in case of action.

Use your best endeavors to make the surgeons and mates of the regiments attentive to their duty.

For any debts contracted for the use of the general hospital, agreeable to the above rules, draw on me. You will employ the same person to supply fresh meat and at the same prices, as in the hospital at New York.

Weekly returns of the sick to be sent over early every Monday morning as usual.

Be pleased to call on Mr. Delameter for one hundred additional blankets . . . and as many beds: applying to the quartermaster for straw, from time to time, and order the nurses, washerwomen, etc., to clean them from time to time.

An orderly mate is to take charge of the blankets and bedding, etc., and of the hospital furniture every week: to enter into a book for the purpose, what stores of this kind are given out, to examine what each sick (person) brings with them, and to see that nothing is carried out on their dismissal not belonging to them.

An orderly sergeant, or corporal, or careful soldier (if the general will allow) ought to be stationed at the hospital, to take charge of the arms, etc., of the sick, whilst in hospital, and to give them up on his death or dismissal.

A carpenter ought to attend constantly to make coffins, or to perform other work, for which you will apply to the quartermaster general.

No blankets, or other effects of the hospital, to be expended at the funeral of those soldiers who die in the hospital.

I remain, sir, your most humble servant,

JOHN MORGAN.

3.—REGULATIONS proposed by the Director-General of the Hospital; and agreed upon with the Regimental Surgeons, to be laid before CONGRESS for THEIR DETERMINATION upon them.

First.—That regimental surgeons apply to the quartermaster general and obtain from him, or the barrack master, by an order from him, some proper quarters convenient for the situation of each regimental or brigade hospital.

Second.—That said hospitals be furnished from the quartermaster general's department with necessary utensils and hospital furniture, according to a list of enumerated particulars.

Third.—That regimental surgeon be supplied in future by continental druggists, with medicines, instruments and old linen for bandages, and necessary dressings.

Fourth.—That they shall report to director general or surgeons of the general hospital, all such sick pa-

tients of their regiments, who are proper objects; making use of every possible precaution, to guard against crowding in the hospital with putrid cases, that require fresh air for recovery of the sick; lest hospital, malignant, or pestilential diseases be excited, to the great devastation and ruin of the army.

Fifth.—That they make proper reports from said register, to accompany every person they recommend to the general hospital, with an account of the patient's care, and previous treatment, and what clothing is sent with each patient, certified by the surgeon or mate, and signed also by a commissioned officer.

Sixth.—That they make daily returns to quartermaster or adjutant of the regiment; of the sick belonging to that regiment, who are unfit for duty, whether remaining under their own care, or sent to the general hospital, that no soldiers may be exempt from duty, as sick men, that are not borne on the doctor's list; and that no rations be drawn for them, amongst the effective men, whilst they are drawn for with the sick, whether in the general or regimental hospitals.

Seventh.—That they make weekly returns of the sick from their registers, both in the general hospital, and regimental or brigade hospitals, as well to the director general as to the commandant or brigade, that a true state of the sick of the whole army may be made out, to lay before the Commander in Chief, and to be transmitted to Congress, weekly.

Eighth.—That agreeable to the sick list returned to the director general, the regimental surgeons be entitled to draw from the general hospital, for the sick remaining under their care, any articles they may choose, agreeable to the various diet tables made use of for the patients of the general hospital; and whatever other refreshments they choose, with which the general hospital is supplied, to the full amount of their rations. If they require more from the general hospital, the sick are to be sent to the general hospital.

Ninth.—That Colonels of regiments be allowed to draw monies for defraying any extraordinary or incidental charges of regimental hospitals, and for such articles as are not to be got in the stores of the general hospital, nor in the commissariat or quartermaster's department, and on account of the disbursement to be settled, with the weekly or monthly abstract of the regiment.

Tenth.—That the state of the several regimental or brigade hospitals, of the sick, and of the medicine chests, be subjected from time to time to the director general, or such hospital surgeons as he shall appoint to that duty.

Eleventh.—That in all things, not particularly ascertained in these regulations, the usage of the British and other armies be followed, till otherwise directed as far as is consistent with the good of the service.

One is astonished at the completeness of these regulations, the number of details covered. It is evident that they were not evolved at once, but were taken from the regulations and customs of the British Army. Paper work must have existed long before that time. When the term brigade is used here probably it does not refer to a brigade of several

regiments, but to a small force of a few hundred men, termed a brigade rather than a regiment.

4.—ADDRESS TO THE SURGEONS.

I have, with all care and attention in my power, taken into consideration the state of the regimental surgeons, with a view to getting them provided with regimental hospitals, and pointing out the means for their being in future, supplied with the usual requisites, for the more easy, more regular, and more extensive discharge of their duties annexed to their stations. To answer this end, I have considered that it is within our power, as matters now stand, and what we are to aim at, for further improvement; and have, by a train of reflexions on the subject, been led, in the first place, to propose certain regulations, which appear to me to be both salutary and practicable, if they meet with your concurrence, for which I shall submit them to your hearing and strictures, for correction and amendment. If we can agree in them, it will be one step gained, and may serve as a foundation, on which to proceed, in smoothing every difficulty that may still remain, toward forming a more perfect plan, or model of economy, in the conducting of the military hospital, and providing for the sick and wounded.

The next step I apprehend we have to take, is to apply to Congress for an immediate supply of chirological instruments and bandages, for the regimental surgeons, and for its approbation of the proposed regulations, as well that that of the Commander in Chief; that those regulations may have a proper authority to rest upon, for their sanction and support; and 3dly to suggest such others, as may be still more useful, in future, though the continuance of the war may make further regulations necessary.

5.—“On July 17, 1776, Congress took into consideration the report of the Committee on the memorial of the director general of the American hospital, whereupon, Resolved

First.—That the number of hospital surgeons and mates be increased, in proportion to the augmentation of the army, not exceeding one surgeon and five mates to every five thousand men, to be reduced when the army is reduced, or when there is no further occasion for such a number.

Second.—That as many persons be employed in the several hospitals, in the quality of storekeepers, stewards, managers, and nurses, as are necessary for the service, for the time being, to be appointed by the director of the respective hospitals.

Third.—That the regimental chests of medicine and chirological instruments, which are now, or hereafter shall be in the possession of the regimental surgeons, be subject to the inspection and inquiry of the respective directors of hospitals, and the director general, and that the said regimental surgeons shall, from time to time, when thereto required, render account of the said medicines and instruments to the said director, or, if there be no director in any particular department, to the director general; the said accounts to be transmitted to the director general, and by him to the Congress; and the medicines and instruments not needed by any regimental surgeon to be returned, when the regiment is reduced, to the respective directors, and an account

thereof rendered to the director general and by him to Congress.

Fourth.—That the directors of hospitals in the several departments, and the regimental surgeons, where there is no director, shall transmit to the director general regular returns of the number of surgeons and mates and other officers employed under them, their name and pay; also on account of the expenses and furniture of the hospital under their direction; and that the director general make a report of the same from time to time, to the Commander in Chief, and this Congress.

Fifth.—That the regimental and hospital surgeons in the several departments make weekly returns of the sick to the respective directors in their departments.

Sixth.—That no regimental surgeon be allowed to draw upon the hospital of his department for any stores except medicines and instruments; and that when any sick person shall require other stores, they shall be received into said hospital and the rations of the said sick persons be stopped, so long as they are in said hospital, and that the directors of the several hospitals report to the commissary the names of the sick, when received into and when discharged from the hospitals, and made a like return to the board of treasury.

Seventh.—That all extra expense for bandages, old linen, and other articles necessary for the service, incurred by any regimental surgeon, be paid by the director of that department, with the approbation of the commander thereof.

Eighth.—That no more medicines belonging to the contingent be disposed of till further order of Congress.

Ninth.—That the pay of the hospital surgeons be increased to one dollar and two thirds of a dollar by the day; the pay of the hospital mates to one dollar by the day, and the pay of hospital apothecary to one and two thirds of a dollar by the day, and that the hospital surgeons and mates take rank of regimental surgeons and mates.

Tenth.—That the director general and the several directors of hospitals be empowered to purchase, with the approbation of the commanders of the respective departments, medicines and instruments for the use of their respective hospital, and draw upon the paymaster for the same, and make the report of such purchases to Congress.”

Journal of Congress, July 17, 1776.

(To be continued)

LONDON LETTER.

(From Our Own Correspondent)

Red Cross Societies Meeting.—Conference of the Imperial Bureau of Entomology.—Society for the Prevention of Venereal Disease.—Sir John Bland Sutton Retires.

LONDON, July 19, 1920.

The first meeting of the Medical Advisory Board of the League of Red Cross Societies took place on July 5th, when it discussed with the director general, the general medical director, and the chiefs of the medical department of the league the health work to be undertaken by the league. The board is composed of the following experts: Bel-

gium, Professor Bordet, director of the Brussels Pasteur Institute; Denmark, Professor Madsen, director of the Copenhagen State Serum Institute; France, Professor Ronx, director, and Professor Albert Calmette, subdirector of the Paris Pasteur Institute, and Dr. Leon Bernard, professor of hygiene in Paris University; Great Britain, General Lyle Cummins, professor of pathology, London, Sir Walter Fletcher, secretary of the medical research committee, London, Sir George Newman, chief medical officer of the Ministry of Health; Italy, Professor Bastianelli, pathologist to the Rome Polyclinic, and Dr. Castellani, professor of tropical diseases at the London School of Tropical Medicine; Japan, Dr. Kinnosuke Miura, professor at Tokyo University; South America, Dr. Chagas, director of the Oswald Cruz Institute of Rio de Janeiro; United States, Dr. William Welch, director of the School of Hygiene at Johns Hopkins University, Dr. Herman Biggs, Health Commissioner of New York State and Dr. Simon Flexner, director of the Rockefeller Institute.

* * *

Representative entomologists from all parts of the British Empire assembled on Tuesday, June 1st, at a conference arranged by the Imperial Bureau of Entomology, South Kensington. Dr. Guy A. K. Marshall, director of the Imperial Bureau, remarked that the department was inaugurated in 1909 under the name of the Entomological Research Committee, Tropical Africa, by the then Secretary of State for the Colonies, for the purpose of stimulating the study of the numerous insect pests that were retarding the development of tropical Africa, and especially the blood sucking and disease carrying insects. In 1913 its activities were extended to cover the whole of the Empire, its principal functions being to collect and disseminate all the published information relating to injurious insects, to identify insects sent by entomological, medical, and veterinary officers from all parts of the Empire, to distribute entomological specimens required for research or teaching purposes, and generally to render all possible assistance to economic entomologists in the carrying out of their work against injurious insects.

* * *

The first annual meeting of the Society for the Prevention of Venereal Disease was held at the house of the Royal Society of Medicine, 1 Wimpole Street, London, W., on the evening of Thursday June 3d. The president of the Society Lord Wiloughby de Broke was in the chair. In the course of an able speech in which the objects and aims of the society were recapitulated he strongly condemned the "policy of suppression" adopted by the Government in all matters relating to venereal disease and moved a resolution asking that the Ministry of Health should authorize druggists to supply means of selfdisinfection which they are now prevented from doing by act of Parliament. Dr. Saleeby, who seconded the resolution, said he believed that venereal diseases were on the increase despite official statements and explanations. Sir James Crichton Browne supported the resolution in an eloquent speech. Sir William Arbuthnot Lane observed that the society should be called the sui-

cide club, because it was mainly composed of medical men who by preventing the spread of venereal diseases were taking away their own living. Most of the diseases from which the world suffered could be traced to venereal disease. The resolution was carried.

* * *

Sir John Bland Sutton, the well known London surgeon has retired from the active staff of the Middlesex Hospital with which he has been connected for forty-two years. He has been a generous giver to the hospital. He founded and endowed the Bland-Sutton Institute of Pathology. Sir John was recently made the president of the newly formed association of British surgeons. The Board of Governors of the American Hospital in London gave a dinner on July 6th, at which the guest of the evening was Dr. Charles H. Mayo, of Rochester, Minn. Lord Bryce and Lord Reading were the hosts at the dinner.

* * *

It has just been announced that the scheme for providing a memorial to Sir Victor Horsley has now been given a definite start. The nucleus of a committee has been formed, with Sir Charles Ballance as chairman. Sir Frederick Mott and Dr. H. H. Tooth will act as honorary treasurers *pro tem*, and Sir W. Arbuthnot Lane and Edward J. Donville will act as joint secretaries. In a letter contributed to the *British Medical Journal*, June 5, 1920, Mr. Donville says that Lady Horsley has withdrawn any objection she had previously expressed, and it is hoped to found a lectureship bearing Sir Victor Horsley's name, probably under the auspices of the University of London, but all details have yet to be formulated by the much larger committee which is in course of formation. Sir Victor Horsley was probably the greatest English speaking medical scientist of this generation. His investigations into the surgery of the brain were epoch making and paved the way for the marvellous operations now done in that region. He was essentially a pioneer in medical science and no Englishman who died in the war fighting for country and civilization is more worthy to be remembered.

* * *

With regard to the need for more dentists in Great Britain and the prevalence of dental disease in various forms, the speakers at the Congress of the Food Education Society held in Manchester, on May 13, 1920, emphasized the gravity of the situation. Among these speakers none was more interesting, original, and scientific than Dr. Harry Campbell. In the course of his speech he stated that the public stood in need of four great health reforms, namely, food, dwellings, including satisfactory working conditions, alcohol, and lues. All the political questions of the day are as nothing compared to the urgent need for reform in these four directions. Dr. Campbell said further that perhaps the greatest reform needed in Great Britain was the reform of the faulty dietetic customs of its inhabitants and one of the consequences of these bad dietetic habits, namely, the shocking state of the nation's teeth, which in his opinion were the worst of any nation. The number of dentists in Great Britain was wholly inadequate.

THE FUTURE OF HOSPITALS.

It seems as if the mode of medical practice is about to undergo a change. If the situation in Great Britain be taken as any criterion of other nations a change is coming. It is likely that the practice of medicine in the future will have more of a preventive character than now. This is not to say that curative and remedial treatment will not be employed, but the object will be to diagnose early and to prevent ailments from attaining serious dimensions. Sir James Mackenzie, the British heart specialist, is the pioneer in this departure from traditional methods, and his idea is that the student and the general practitioner should be trained to detect early symptoms. At St. Andrews, in Scotland, he is endeavoring to put his views to practical use. If this method of preventing disease is shown to be successful, it follows that the function of the hospital will change. At the present time the function of the hospital is to take charge of cases which the general practitioner does not think fit to treat. Hospitals afford opportunities for research which are not available under such favorable conditions elsewhere and lastly they provide the means for teaching students. It is obvious that the most important function of the physician is to diagnose correctly.

Comparatively little disease is detected in the hospital. Only serious cases are sent in, for if slight cases are admitted they are not or should not be kept long. The great proportion of early disease is seen in general practice; only when disease is estab-

lished is the patient deemed a fitting inmate of a hospital. Therefore hospitals should be employed mainly as centres for diagnosis and when diseases have been recognized the sufferers therefrom should be sent to the country to be treated and cared for. This would be an economical procedure. Rents in the country are considerably lower than in the city, fresh air abounds and a pleasant environment is accessible. By these methods medical education might be directed into more productive channels and more in keeping with the latest views.

There would be no need of the palatial buildings which are now considered necessary for these institutions. The money that has been thus expended in bricks and mortar, and especially in this country during recent years, might in many instances have been put to better purpose. The war has taught the value of the hutted hospital, which in the country is more suitable and comfortable than the magnificent buildings which are erected in the big centres of population. The conception of the functions of the hospital held by many who have made a life long study of the subject is not as a place in which treatment for an indefinite time may be given or in which those suffering from organic diseases may linger until death releases them, but as an institution in which certain medical and surgical cases may be treated, and above all as medical clearing houses. The scheme is as yet only in embryonic form and doubtless is surrounded with many difficulties. It may never develop and certainly will be subjected to much destructive criticism. On the other hand, none of the difficulties appears to be insuperable and even if discussion is aroused as to the true functions of the hospital, the question will not have been in vain. The hospitals as they are now are by no means perfect and the hospital of the future must be a revised edition of the existing institution.

GENERAL EFFECTS OF SUPRARENIN.

The general effects of left suprarenin are similar to those of other bodies of the same group. All these substances exhibited in toxic doses produce death from pulmonary edema, which occurs within a few minutes or several hours later. The cause of this edema is not clear. Some writers attribute it to excessive pressure; Gerhardt maintains that it exercises a nefarious action on the heart, especially the left heart, while Hallion admits that adrenalin attacks the endothelium of the pulmonary vessels. It is clear in all experimental work that it is pulmonary edema which kills the animal, and in his

many experiments Loup, of Geneva, is particular to state that he never met with cardiac fibrillation. It seems certain, however, that the mechanism of the edema is different in the case of rapid and of tardy death. In the former the serious cardiac disturbances which accompany excessive pressure are sufficient to explain the accident; in the latter the edema occurs at the time when the pressure has fallen to normal for some time and the heart beats are regular. It would therefore seem as if the pulmonary edema was simply the last phase of more complex phenomena. It may be that its cause should be looked for in a change of the pulmonary endothelium, since at the time the edema arises there is present a cardiac disturbance which explains its occurrence.

Death is preceded by manifestations of muscular paralysis of central origin, all this group of substances producing them, although they are more intense from left suprarenin. Naturally it is in tardy death that they are more easily observed. The animal often languishes for hours without being able to move and responds hardly at all when excited. Nevertheless, it is rare that he is incapable of any movement, as the paralyzes are generally incomplete, while their intensity varies during the progress of the intoxication. They usually increase up to the time of death and when this takes place the animal will have been an instant in complete inertia. Tardy death appears to be at least partially due to gradual weakening of the central nervous system, and this opinion is confirmed by the fact that at the time of death the asphyxia resulting from the pulmonary edema produces only very weak convulsions, sometimes none, and that strychnine no longer has any action on the profoundly depressed animal. The sensibility appears to be almost wholly preserved excepting in the last stages of the intoxication. Finally, there is an inconstant glycosuria, with salivation and occasionally dilatation of the pupils. The respiration, which is suspended for an instant following the infection, begins again superficially and rapidly. Occasionally the dyspnea is interrupted by a series of deep, slow respirations which last only for a few minutes. Surely lethal doses cause death quickly, while weaker doses—which some animals resist—kill more slowly.

Briefly, it would seem as if this group of substances kills rabbits either rapidly from cardiac disturbances set up or tardily by progressively increasing paralysis of the central nervous system, although in each case pulmonary edema is the immediate cause of death. All the substances belonging to this group produce the same clinical picture. The lethal dose varies.

Aberhalden and Glava have studied the toxicity of right and left suprarenins in mice by subcutaneous injection. Left suprarenin kills the animal at a dose of one tenth milligram, while one centigram of right suprarenin is necessary to kill. The latter should consequently be one hundred times less active than the levogyric form. This difference with the results arrived at by Loup may be due to the matter of introducing the drug as well as the species of animal used for the experiments. Mice, like rabbits, die either a few minutes following the injection or after some hours. They present complete muscular paralysis and a considerable drop in temperature. At the time of death the temperature falls to 20° C. Loup, experimenting with rabbits, never met with a temperature lower than 34° C.

PHYSICIAN AUTHORS—DR. JOHN McCRAE

The World War seems to have reawakened a universal interest in the Muse and apparently the interest has not yet reached its uttermost heights. This interest is manifested in two directions. First, the output of new poetry is so great and of such quality that an impression is arising that another golden age of poetry is at hand. Second, books of poetry are selling as they never sold before—single limited editions no longer are the rule; nor do the volumes grow dusty and worn on the shelves of the shops. Psychologists can give you elaborate reasons for all this, but those reasons need not be set down here.

Scarcely had war's first tocsin sounded when this remarkable reanimation of the Muse began. Thereafter throughout the course of the conflict there was a steady flow of poetry, good, bad and indifferent. Most of it is doomed to oblivion—is already forgotten—but there is one poem that was born of the terror and suffering at the front that the world will never forget—Dr John McCrae's *In Flanders Fields*. Unquestionably this is the great outstanding poem of the war period, the most widely read, the most widely quoted of all. Who has not heard it recited from platform, pulpit or stage during bond drives and war gatherings of all descriptions? The souls of mankind often have been stirred to great emotional heights by the versifier's fervor and skill, but it is doubtful if in the whole realm of literature any other bit of verse ever was so successful in firing the hearts of humanity.

If ye break faith with us who die
We shall not sleep, though poppies grow,
In Flanders fields.

Whatever its merits as poetry, *In Flanders Fields* is assured of immortality. Its historical

association has given it a permanent place in literature. It gave expression to a mood that was well nigh universal and will remain as a permanent record of that mood, now that it has passed away. Dr. McCrae's fame will rest on this single poem, just as surely as the fame of Charles Wolfe rests solely on *The Burial of Sir John Moore*. McCrae's other poetry is meagre—one slender volume holds all of it—and, although it reveals here and there the touch of the true poet, it is not remarkable as poetry. The volume also contains some of Dr. McCrae's prose writings, mostly extracts from diaries and letters. He wrote many essays on miscellaneous subjects and many contributions to medical publications, but these have not been collected. Other than the volume of poetry, the only book that bears his name is a *Textbook on Pathology*, of which he and Professor Adami of McGill University were coeditors.

Writing was distinctly a pastime with Dr. John McCrae, his biographer tells us, adding that medicine was his main concern in life, in the profession of which he spent twenty years in study, practise and teaching. He was said to be a born teacher. When he was graduated from the medical school of the University of Toronto in 1898 he was the gold medallist of his class. He began his career in medicine as an intern in Toronto and Baltimore hospitals, but interrupted this work to get his first taste of war. This was in South Africa in 1899 and 1900, where he was a lieutenant colonel of artillery during the Boer War and won the Queen's Medal with three stripes. A number of his poems were inspired by his experience on the veldt. After his return from South Africa he resumed intern work, but soon accepted a professorship in pathology at McGill University. For several years he also was professor of pathology at the University of Vermont.

McCrae was one of the martyrs of the war. He was aboard ship on his way to London when the war broke out. Immediately upon disembarking he cabled home, offering his services, and was appointed by his old friend, Major General Morrison, to be surgeon of the First Brigade, Canadian Artillery, in which capacity he served throughout the fighting along the Ypres sector, where the Canadians covered themselves with glory. He was under intense shell fire often, for periods of many days, and his brigade was behind the area where the first gas attack was launched. In his diary he gives a graphic description of their moving up to hold the front line trenches. It was during his fourteen months with the Ypres guns that he wrote *In Flanders Fields*, which was first published in *Punch*.

Overwork and the conditions under which that work had to be performed, undermined his health and he was finally persuaded to leave the front and accept a transfer to a base hospital, where he served two years. In the performance of his duties he was stricken with pneumonia, complicated by meningitis, and died after five days' illness. McCrae came of old Scotch stock that emigrated to Canada about the middle of the last century, settling in Guelph, Ontario, where he was born in 1872.

A PROBLEM.

A recent perusal of Charles Reade's *Hard Cash* created a lively feeling of gratitude to all legislators, philanthropists, and authors who had brought into glaring, uncompromising daylight the inmates of our lunatic asylums. There were those competent, but debarred from speaking for themselves; those bullied into greater debasement, whose every word was disbelieved by men in authority, and usually ended in becoming what their keepers said they were. Now the doctors, in danger of being driven mad themselves by overwork, answer the legislators and philanthropists by demanding more trained help, more buildings, more prophylaxis. A man is found incapable on the street by a policeman. His behavior is eccentric. Is he mad, drugged, or drunk? The doctors say that policemen should be trained to discriminate. A man is certified as mad and committed to an asylum where he associates with many far worse than himself. The medical committee demands trained keepers, budding alienists with the patience of Job, to observe the men. You say the insane are capable of being taught habit formation. Send us proper teachers who will adapt their teachings to each man's ability. This is not doctor's work.

There are thousands of delinquent boys and girls who for their own protection and that of society must be confined. The old plan was to term all of them idiots or wanting. Now there are a dozen fine distinctions. Train teachers, train nurses, send them to help the doctors. Thousands of mentally deficient girls add to the population every month, and the doctor, a democrat when an obstetrician, opens the gates of life as politely to a weary faced little idiot as to a plump young Hercules. But his cry is, send settlement workers, send lecturers, send reformers of homes to spread the knowledge of evitable evils; not ours the tremendous task of grappling with the evils an educated public should provide funds to prevent. Whether insane or criminal, a test, an analysis, is now demanded. There are many

who should be transferred to the asylum from the prison, many who should go to prison. But who is to decide wisely unless a mighty band of competent people are trained to go on the institutional staff, and who is to find the money? Are the helpers to be paid as generously, as adequately, as the overworked doctors who try to do all the social reformers imagine it is the doctor's work to carry out?

The lunatics, idiots, feeble-minded form only one section of those demanding medical care. Open war is declared against the venomous, devastating trio, cancer, tuberculosis, syphilis, while influenza gathers fresh forces every year. The doctor is also required to cooperate with the engineer in rendering new lands habitable, in determining healthy conditions for those who submarine, for those who super-terrate, and as yet their number of skilled assistants is pitifully small. The doctors' protest against more work is no mere petty, selfish consideration for themselves or righteous demand for more money, but the protest of those who realize what ought to be done yet cannot do it.

EXPECTANT INDIA.

With the courtesy and patience characteristic of the Indian, statements of the urgent need for medical reform have been put before the British authorities during long years. The latter urge that no real help would be given to the millions committed to their care by giving them half-trained medical men and that funds are lacking for furnishing any appreciable increase in the supply of qualified ones. Even if more medical schools and colleges are to be opened, the pay, position and prospects are so poor that they militate against the popularity of the service. There is no inducement for a young doctor to take up rural practice in the government dispensaries. He gets no practice, all minor ailments being sent to bigger medical institutions, and no surgical equipment—not even a stove or sterilizer being provided, whereas hydrocele, anal fistula, piles, buboes, amputations, could be treated if proper equipment were provided. Knowledge rusts for want of use, and a listless laziness assails the young doctor. There are two species of medical men, one possessing university qualifications, the others diploma holders from a governmental or competent examining body. The present anomalous position of medical graduates and diploma holders should be at once done away with. The standards of minimum qualifications for admission in the different provinces vary and this is greatly due to the absence of a General Medical Council for India to control the medical education of the whole country. The minimum qualification for admission into any institution should be laid down by the Council, and recruitment to the Civil Medical Service be by open competition. The postponement of some of the most pressing health reforms is due to the paucity of medical men. There are hundreds who

eagerly look to medicine for an honorable career, but the institutions for learning are so few, the accommodation in these so limited that numbers have to be turned away.

WEALTH AND HEALTH.

The Industrial Fatigue Research Board of England has put forth one excellent report after another shedding light on the human machine in industry. Some of its studies are general, others deal with particular industries. The latest report, by Dr. H. M. Vernon, is on *The Speed of Adaptation of Output to Altered Hours of Work*. Commenting editorially on Dr. Vernon's findings, the *Lancet* says:

"These facts suggest that there is a certain amount of energy at the daily disposal of the human machine; that there is a definite urge forward to expend this energy, an urge due to the anabolic activity of rest stimulating the katabolic activity of work; and that when the two balance one another a level of productive activity is maintained. Practice may increase productivity still further, but practice only consists in using energy economically, so that more things are made with the same exertion previously required for making fewer. Interest also centres on the fact that quicker work during shorter hours is associated with less lost time (represented by sickness), from which health appears to be a function of activity; and, from the viewpoint of health, there appears to be an optimum rate of activity for the human organism which seems to coincide with the optimum rate of production. The Industrial Fatigue Board will indeed justify its existence if it is able to convince those who control the destinies of the industrial world that material wealth and individual health depend, so far as labor is concerned, on the same factors."

News Items.

Cannot Prescribe Whiskey for Yourself.—Under a new ruling of the Bureau of Internal Revenue, medical men cannot make out prescriptions for whiskey for themselves, even though they are sick.

Loyola University Appointments.—Dr. Charles Louis Max has been appointed professor and head of the department of medicine and Dr. Edward L. Moorehead has been appointed professor and head of the department of surgery in Loyola University School of Medicine.

Surgeon Lavinder Named Assistant Surgeon General.—Senior Surgeon C. H. Lavinder, formerly in charge of the hospital division of the U. S. Public Health Service, has been named assistant surgeon general and is now in charge of the division of hospitals and relief.

Poliomyelitis Increasing in Boston.—An increase in the number of cases of acute anterior poliomyelitis is reported in Boston. There were seventeen cases in that city between January 1st and July 1st, sixteen cases during July, ninety-four in August, and sixty-three for the first nine days of September.

Hospital Bequests.—The will of the late Congressman Colonel Thomas W. Bradley, of Walden, New York, leaves \$5,000 to St. Luke's Hospital in Newburgh, and \$5,000 to the Thrall Hospital in Middletown.

Death of Indian Medical Editor.—Lieutenant Colonel William Dunbar Sutherland, imperial serologist to the Government of India and formerly editor of the *Indian Medical Gazette*, died June 27th in Calcutta, at the age of fifty-three.

Hospital Association Meeting.—The American Hospital Association will hold its twenty-second annual conference October 4th to 8th at Montreal. In connection with the meeting there will be reports from the American Conference on Hospital Service.

Hospital Bequests.—The will of the late Berthold Bendheim, of New York provides the following bequests to hospitals: \$2,000 each to the Mount Sinai Hospital and the Montefiore Home; \$500 each to Beth Israel Hospital and St. Mark's Hospital.

New York State Health Conference.—Dr. Guy H. Turrell, of New York, was elected president of the conference of New York state health officers and public health nurses, held recently at Saratoga Springs. It was decided that the 1921 conference will be held at Ithaca.

End Latvian Relief.—The child feeding work of the American Relief Administration in Latvia has been terminated. That country now has sufficient food to meet its needs, and in addition the government has built up an effective child welfare system that will continue whatever relief is necessary.

United States Civil Service.—The United States Civil Service Commission announces an examination for microscopist in the office of the surgeon general, Army Medical Museum, Washington, D. C., at \$1,800 a year plus a bonus of \$20 a month. Receipt of applications will close October 19th.

Public Health School at Georgia University.—A School of Public Health and Hygiene is to be added to the medical department of the University of Georgia, at Augusta. Dr. C. C. Applewhite, P. A. Surgeon, U. S. Public Health Service, has been detailed to Augusta for the purpose of starting the school.

For Ratproof Buildings.—At a recent conference of public health officers at Beaumont, Texas, to discuss bubonic plague, recommendations were made to Surgeon General Hugh S. Cumming that the Public Health Service draw up standard specifications for ratproof buildings and furnish these to the different states and cities for incorporation in building codes throughout the country.

Delegates to Antialcoholism Meeting.—Governor Smith, has appointed delegates to represent New York state at the Fifteenth International Congress Against Alcoholism, to be held in Washington, September 21st to 27th. The following medical men are among those named: Dr. Charles W. Pilgrim, chairman of the State Hospital Commission, of Albany; Dr. Mathias Nicoll, Jr., deputy commissioner of health, Albany, and Dr. Pearce Bailey, of Katonah.

Pellagra Hospital to Be Discontinued.—The Pellagra Hospital at Spartanburg, S. C., maintained by the U. S. Public Health Service has been discontinued because the disease has been practically wiped out in that locality. The equipment will be distributed among other hospitals of the Public Health Service.

Railway Surgeons Elect Officers.—Officers have been elected as follows by the Baltimore and Ohio Association of Railway Surgeons, recently in convention in Baltimore: President, Dr. E. B. Fittro, of Salem, W. Va.; vice-presidents, Dr. J. G. Shirer, of Newark, Ohio; Dr. V. D. Lespinasse, of Chicago; secretary-treasurer, C. E. Johnson, of Baltimore.

Death of Sir William Babbie.—Lieutenant General Sir William Babbie, V. C., of the British Medical Service, died the early part of September while spending a holiday in Belgium. He was sixty-one years old. Sir William Babbie served as principal director of medical services in 1915-16 in Gallipoli, Egypt and Salonika and later as director and inspector of medical services at the War Office.

Navy Drops Whiskey as Medicine.—Spiritous liquors are to be dropped from the supply table of the medical department of the Navy, according to an order recently promulgated by the Bureau of Medicine and Surgery prohibiting their issuance to naval vessels for medicinal purposes. Medical supply depots may issue whiskey only to hospitals, and when the present supplies have become exhausted, whiskey will be banned entirely. The order states that when whiskey is no longer available and a medical officer deems alcoholic stimulation absolutely essential for the preservation of human life, the ethyl alcohol obtainable from supply officers may be prescribed. This alcohol conforms in all respects with the requirements of the United States Pharmacopœia. The order directs that no further purchase from any source be made of distilled spirits, wine or alcohol preparations. It is estimated that the supply on hand will last only two or weeks.

Personal.—Dr. James M. McTiernan has removed his office to Euclid Hall, Broadway and Eighty-sixth street, New York.

Dr. George Chaffee, formerly of New York City, announces the opening of his office at 100 Hawley street, Binghamton, N. Y., practice limited to operative bone surgery, maternity cases, and to consultation.

Dr. John W. Moore has been elected full time professor of research medicine in the medical department of the University of Louisville, Kentucky.

Dr. Leonard G. Rowntree, professor of medicine in the medical school of the University of Minnesota, and Dr. Reginald Fitz, associate in medicine of the Massachusetts General Hospital, have joined the staff of the Mayo Foundation and the Mayo Clinic at Rochester, Minn.

Dr. J. G. Adami, F. R. S., Vice-Chancellor of the University of Liverpool and lately Strathcona professor of pathology and bacteriology in McGill University, Montreal, has been elected to an honorary fellowship at Christ's College, Cambridge, of which he was formerly a scholar.

Proposed International Health Office.—The Council of the League of Nations has recommended for formal adoption at the General Assembly of the League in November the proposal for an international health office prepared at the recent London conference. The London conference of public health experts made a series of detailed recommendations regarding the functions and duties of the proposed organization, the incorporation within it of the existing *Office Internationale d'Hygiène Publique* established under the Rome Convention of 1907, and the nature of the permanent machinery which the new international health office would require.

Death of Professor Gautier.—Dr. Armand Gautier, professor of chemistry in the Faculty of Medicine of Paris and director of the laboratory of biological chemistry, died July 27th at Cannes, France, at the age of eighty-two years. He was the discoverer of leucomaines, and he studied with equal success many other problems relating to cell tissue and general hygiene. He made the discovery of arsenic as a normal element of animal tissues, of free hydrogen in the air, of iodine in the land algæ, of the genesis of mineral waters, of the rôle of fluorine, and of a new method of preparation and therapeutic application of certain organic compounds of arsenic.

Acid Test for Chauffeurs.—Due to the frequency of automobile accidents in New York city, Health Commissioner Royal S. Copeland has written a letter to Secretary of State Francis M. Hugo suggesting amendments to the Sanitary Code which will make it impossible for persons with defective sight or hearing or those addicted to narcotic drugs to become chauffeurs. Dr. Copeland pointed out that 398 people had been killed by automobiles in the first seven months of this year and that 767 lost their lives in 1919. Out of 7,464 self confessed drug addicts registered with the health department, 534 were listed as drivers or chauffeurs. Dr. Copeland also stated that many chauffeurs had defective sight or hearing.

Health Department Plans More Consultation Clinics.—The Group Consultation Clinic held during the week of August 22nd at Goshen, N. Y., proved so successful that the State Department of Health is planning similar clinics for other localities. Dr. E. C. Body is quoted as follows in the daily press regarding the conduct of the clinic:

"Patients are referred to the clinic by their attending physician. After a careful history of the case the patient is referred to the proper consultant for examination. If the consultant thinks that additional information is necessary before a diagnosis is made, such as laboratory examination or an x ray examination or examination by another consultant, the case is referred to that department.

"When the examinations are completed the consultant reviews all the evidence, makes his diagnosis and any recommendations concerning the future course of procedure for the patient. All this information is then forwarded to the patient's attending physician. It is obvious that under this arrangement the relation between the patient and family doctor is not altered in any degree, and that the clinic is conducted along ethical lines."

Insanitary Dairy Conditions Found.—Investigations conducted by the Bureau of Foods and Drugs of the Department of Health of New York city have disclosed insanitary dairy conditions which are considered contributory to the high bacterial content of Grade B milk. According to a letter from Mr. Ole Salthe, acting director of the bureau, to the New York Milk Conference Board, milking machines were improperly cleaned between milkings, clean milk cans were not allowed to air, milk was insufficiently cooled, milking utensils were not properly washed, and in several dairies dirty stables and cows were found.

Proposed Hospital for Insane Soldiers.—Plans are under consideration by state officials for the erection by New York state of a hospital for insane soldiers, the hospital to be operated and maintained under the supervision of the War Risk Insurance Bureau. An appropriation of \$1,000,000 will be asked of the Legislature for this purpose. At the present time there are in the state about 900 former service men who have become insane. Of this number 474 are in state hospitals and the rest in other institutions. The need of such a hospital is evidenced by the overcrowded condition of the state hospitals for the insane.

Civil Service Examinations.—The New York State Civil Service Commission announces examinations, written or unwritten, for the following positions: medical examiner and assistant medical examiner, State Industrial Commission, \$2,000 to \$2,800; physiological chemist State Department of Health, \$1,650; sanitary supervisor, State Department of Health, \$3,500; laboratory assistant in bacteriology, State Department of Health, \$1,500; assistant in pathology, State Institute for the Study of Malignant Disease, \$2,500; dentist, State Hospital Service, \$1,200 to \$1,500; first assistant physician, Letchworth Village, \$2,500 and maintenance; psychologist, New York State Reformatory for Women, Bedford Hills, \$1,000 and maintenance; supervisor of child hygiene centres, State Department of Health, \$3,000; supervisor of tuberculosis hospitals, dispensaries, and clinics, State Department of Health, \$3,000.

Died.

COMFORT.—In Port Dalhousie, Ont., on Monday, September 6th, Dr. John Harris Comfort, aged ninety-three years.

COX.—In Stanford, Va., on Friday, July 30th, Dr. J. Edward Cox, aged fifty-two years.

GERRISH.—In Portland, Me., on Wednesday, September 8th, Dr. Frederick Henry Gerrish, aged seventy-five years.

MC GUIRE.—In Dobbs Ferry, N. Y., on Sunday, September 12th, Dr. George Harrington McGuire, of New York, aged fifty-eight years.

MORGAN.—In Hadlyme, Conn., on Monday, August 30th, Dr. John Morgan, of New York, aged seventy-five years.

O'DAY.—In Dover, Del., on Tuesday, September 7th, Dr. Edward Francis O'Day, aged fifty-four years.

RYAN.—In Glendale, Cal., on Thursday, August 19th, Dr. Lee Mathew Ryan, aged thirty-seven years.

STOUT.—In New York, N. Y., on Tuesday, September 7th, Dr. Stephen V. W. Stout, of Jersey City, N. J., aged seventy-four years.

THOMAS.—In Cambridge, Mass., on Saturday, September 4th, Dr. Charles Holt Thomas, aged seventy years.

Book Reviews

THE PSYCHOLOGICAL INTERPRETATION OF RELIGION.

Religion and the New Psychology. A Psychoanalytical Study of Religion. By WALTER SAMUEL SWISHER, B.D. Boston: Marshall Jones Company, 1920. Pp. xv-261.

The time is ripe for a book such as this. There are signs of the awakening of interest in psychoanalysis in every department of life; there is active inquiry into its practical value. In this case the new psychology has as much relation to religion as to any so-called secular province. Swisher's conception of religion is that of a certain department or phase of human interest which cannot be detached from the whole. Religion to him is one of the means by which life may attain that freedom of expansion in which alone lies the realization of well being and of satisfying activity.

In his broad study of religion he shows it as a means by which this end may be attained, but at the same time it may be used only to fix more firmly the factors which obstruct freedom. Religion has worn different aspects throughout history. That its more conspicuous later day function is an ethical one does not blind the writer to the element of wish fulfillment in self-protection and in sexual need which forms its source. Long before ethics played a part man created his religion to support and satisfy him in a world of undesirable or difficult reality. Swisher, examining the content of the unconscious, gives ground for his assertion that "religion is primarily emotional and is thus, in the broadest sense, of sex origin."

He discovers in early man the need to be freed from a sense of helplessness and of the bondage of his own powers. This is the content of the later sense of sin. The writer confesses that he differs somewhat from Freud in not accepting the early fear of one's own impulses as the origin of the sense of sin. Freud would see an ethical sense arising in man's earliest experience. Here it is that religion and psychoanalysis manifest sameness of aim and that psychoanalysis enters to interpret the function of religion and to guide its function in accordance with the more scientific needs of the present time. Both seek to free the repressions and permit the individual a realization of his elements of power and freedom in their use. It is psychoanalysis which has discovered the existence of repressions and the hemming of power through them and which adds to the older methods of religion its principles of investigation and readjustment.

Swisher presents in interesting comparison the forms and methods with which religion has helped man toward this end. Examples of the misinterpretations of religion which have tended toward fixations and repressions are prominent in the Christian religion in some of its phases and exponents. Often religion has been only the opportunity for the play of certain neurotic traits. The writer makes his position plain: these are not necessary results of religion. Religion may, however, be joined to a neurotic character and furnish fruitful opportunity for the development of neurotic features. Here the province of religion is enlightened

by psychoanalysis. Originally religion sought chiefly the setting right of the individual with unknown powers; now the emphasis is laid upon his social relations.

The author has discussed in brief but sprightly fashion a number of problems which have always perplexed men. He turns the broad light of the unconscious upon the mystic experience in religion, upon the occult and its prominence in belief. He treats with special clearness the psychology of the various forms of healing associated with religion as he does that of conversion. Free will and determination in religion are presented in the light of the new psychology; so also is man's relation to the problem of evil. The author makes a rightful distinction between evil without or cosmic evil and that within and shows the relation of each to man's individual psychic freedom or repression. In brief the book is a lively presentation of old mooted points in religion, giving them new life and an illumination as to their origin and significance in man's psychic life. At the same time it presents the facts of psychoanalysis in a simple fashion which should make an authoritative and stimulating appeal to the general reader. Sometimes these psychoanalytical facts might be more deeply pressed into or the implication in regard to religion might be pressed further. Nevertheless the author has spoken fearlessly. Such a book, in the style in which it is written, must do much to fasten attention upon psychoanalytical advance and at the same time render service in the explanation and maintenance of the essential in religion.

FROM THE RUSSIAN.

An Honest Thief and Other Stories. By FYODOR DOSTOEVSKY. From the Russian by CONSTANCE GARNETT. New York: The Macmillan Company, 1919. Pp. i-325.

The Chorus Girl and Other Stories. By ANTON CHEKHOV. From the Russian by CONSTANCE GARNETT. New York: The Macmillan Company, 1920. Pp. iii-301.

Letters of Anton Chekhov. With Biographical Sketch. Translated by CONSTANCE GARNETT. New York: The Macmillan Company, 1920. Pp. i-416.

Until recent years there has been a paucity of translations into English of representative Russian literature. Tolstoi, Turgenev and Gorky were among the most frequently read of the writers, while Gogol, the father of modern Russian literature, Dostoevsky, the master of all writers, and the incomparable Chekhov, who is without a peer in the realm of short story writers, received little consideration among English readers in America. In England translations from the works of these writers were more frequently encountered.

The influence of Chekhov is being felt today more than ever before among English writers. It may be said without exaggeration that his works today exert an influence similar to that of Henry James in the same field a decade ago. All this before he has been widely read by the public at large. His plays, with their rich symbolism, are more influential in their effect upon English writers than his short stories. Didactic professors and the no less didactic critics have given Maupassant a clear field in the realm of short story telling; Chek-

hov received scant consideration. There is little to compare. The French writer is decadent, while the Russian presents life and people meeting life. Progress on the one hand, smug mouthings on the other. In our Anglo Saxon prudery Maupassant has spiced many dull hours for us but he has done little else. Chekhov has given us warmth and movement, ever forward, ever in close contact with human, very human beings. On the one hand an incipient disease, on the other, a solid healthy growth.

Reading the letters of Chekhov we get nearer to the man, and such a man! His was a constant struggle—poverty, the difficulties of his profession, and tuberculosis. Through all this we find him optimistic, rarely introverted, always productive, and giving of himself and his abilities to the world. Through his constant activities he acquired an understanding of men and their problems. Whenever difficulties were to be faced he did not shirk his responsibilities. During epidemic and famine we find him working far into the night alleviating the sufferings of his neighbors and he always found time to do the thing he most wanted to do—to write. This active life of his should be a splendid lesson to those whose chronic complaint of not being able to do the thing they most want to do becomes a melancholy whine, and to those who shift the responsibility of their own shortcomings, in surroundings that are excellent in comparison with those under which Chekhov, the sick man, labored. Tolstoi is credited with saying that Chekhov's medicine cluttered up his writing. This may be true, but it is difficult to contemplate what it would have been if he had not had his medicine. Perhaps it would be more fitting to say that Tolstoi would have had a more tolerant understanding of life and men if he had had the medical experiences of Chekhov.

The Chorus Girl and Other Stories contains an excellent collection of Chekhov's tales. His letters are a mirror of this splendid man. They are candid, full of enthusiasm and show a healthy outlook toward life. They are not imbued with sickly sentimentality, nor are they filled with self pity. They should not remain unread by anyone who is interested in literature or its makers.

Fyodor Dostoevsky! For many this is enough. When the rubbish of accumulated writing has been swept aside, in generations to come he will stand out boldly and clearly in sharp relief. In his works we find a giant struggling to express his own difficulties and through his constant battles finding insight into the problems of those around him. Poverty, epilepsy, gambling, and other supposedly non-social traits were his to overcome. From a timid boy he became a swaggering hero flattered by the success of his first works. He imagined himself a radical and was sentenced to death for what would today be considered less than a misdemeanor. At the last moment a courier brought the news that changed his sentence to imprisonment in Siberia. New sufferings and new insights followed. He became a broken man and his sensitive soul was beaten and bruised. He begged for mercy, and through influential friends came release, with new

adventures ever filled with despair and sadness. Then out of the press came his golden works.

In *An Honest Thief* and other stories we find a rather versatile collection of tales, some in the lighter vein, all with a fundamental psychological insight. The second of the series, *Uncle's Dream*, is wonderful in construction and very Russian in its concept. Some of the other stories have a more universal concept. The last story in the volume, *The Dream of a Ridiculous Man*, shows a splendid phantasy in which he portrays an ideal world—his ideal world. Here he goes back to childhood for his material, back to the past, and portrays a world as he would have it in the future.

Those of us who desire more than a flippant story, who desire a tale beautifully told, cannot do without Dostoevsky and Chekhov. If it is only a narcotic we are seeking, something we can easily read and quickly forget, we do not want to trouble ourselves with men of this calibre. For those of us who need this and nothing more these men have labored in vain and it may be said in truth that their works are much too good for us.

PERSONAL AND COMMUNITY HYGIENE.

Healthy Living. How Children Can Grow Strong for Their Country's Service. By CHARLES EDWARD AMORY WINSLOW, D. P. H., Professor of Public Health, Yale Medical School, and Curator of Public Health, American Museum of Natural History. Enlarged Edition. In Two Volumes. With Chapters on Physical Exercises and Sport and Health, by WALTER CAMP. New York and Chicago: Charles E. Merrill Company, 1920. Pp. iii-405.

There were one or two volumes which used to figure in our childhood's reading, chiefly about deportment, manners, and morals. There were good little children who kept themselves clean and gave pennies to the poor, and poor contented children, who knew their "station in life," and were duly grateful to the rich donors of pennies. The volumes before us would have been as much treasured as story books. They would have told us so much we did not know about our mysterious insides, the top part which had to have poultices on, and the lower, all stomach, which had griping pains and required shuddery remedies. We do not know whether the volumes are to be used as class books; we recommend them for private perusal with an offer of explaining the unfamiliar words afterward. There are questions at the end of each chapter which the thoughtful child will use; the physical exercises are easily learned. The chapters on Our Unseen Enemies, Some Undesirable Neighbors, Bad Habits, Fuel for the Body are easily understood and the meaning of such words as pasteurize gratefully explained. Some of the don'ts will irritate socialist fathers. "Stealing rides, coasting and roller skating in the streets are dangerous amusements." "Why do we have to play in the streets, Daddy?" asks the young reader. Clean clothes, daily washing of the body, ventilated rooms, are not always possible, even in apartment houses, where the bleaching green is often a network of strings across the back windows and the bathroom shared with the numerous offspring by one or two lodgers.

But it is the duty of an author to say what should

be done even though he sees no chance of his advice being followed. The ideas of cleanliness and good health may fall on good soil and breed distaste for a condition of things that tired mothers and fathers regard as inevitable.

The second volume seems destined for senior scholars and young teachers, though they may profess to have done the subject already. The chapters on the digestive system, hygiene of foods, care of the skin, germs, tuberculosis, municipal sanitation, the health board and its work, contain much they have forgotten. The idea is good, too, of not preaching health that one may lead a healthier life for the immediate benefits to self, but by showing forth its benefit to provoke and foster emulation and bring about municipal reform. To those of all ages looking back is encouraging. We can all recall conditions which today would not be tolerated, and there will always exist those who daily lament things as they are or disparage the bold adventures into the wild lands of ignorance, yet do absolutely nothing themselves except find fault.

SKIN DISEASES

Handbook of Skin Diseases. By FREDERICK GARDINER, M. D., B. Sc. (Public Health), F. R. C. S. E., Lecturer on Skin Diseases, University of Edinburgh. New York: William Wood & Co., 1919. Pp. 1-160.

The usefulness of these little manuals is more evident today, when the learned laity are more and more inclined to self treatment. This book will be a help to the young doctor who has not had time to keep his dermatology well brushed up. Yet he should ever bear in mind the interrelation of disease and not be content with treating effects. The chapter on tuberculosis brings in the wide question of radiotherapy. Some wonderfully clean healings of tuberculous sores have been effected with the ultraviolet rays, sores that had existed for over a year. Warts on the chin disappeared after three ray treatments. Syphilis is another big question which the author could not omit even from an elementary volume, but he wisely admits the inadequacy of a lecture and refers the reader to the result of a thorough examination by the best men procurable.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

REPUTATIONS. Essays in Criticism. By DOUGLAS GOLDRING. New York: Thomas Seltzer, 1920. Pp. vii-232.

WOMAN AND THE NEW RACE. By MARGARET SANGER. With a Preface by HAVELOCK ELLIS. New York: Brentano's, 1920. Pp. xi-234.

TEN MINUTE TALKS WITH WORKERS. From *The Times* (London) *Trade Supplement*. Garden City and New York: Doubleday, Page & Co., 1920. Pp. viii-203.

OCCUPATIONAL DISEASES AND THEIR COMPENSATION. With Special Reference to Anthrax and Miners' Lung Diseases. By FREDERICK L. HOFFMAN, LL. D., Third Vice-President and Statistician, The Prudential Insurance Company of America; Member National Conference of Social Work, etc. Newark, N. J.: Prudential Press, 1920. Pp. iii-45.

KREBSBÜCHLEIN FÜR ANGEHENDE PRAKTISCHE AERZTE. Zürich: Hans Rhaue, 1920. Pp. i-69.

DWELLERS IN THE VALE OF SIDDEM. By A. C. ROGERS and MAUD A. MERRILL. Boston: Richard C. Badger, 1920.

AGLOHALLUCINOSIS. Von S. GALANT. Mit 8 Abbildungen un Text. Berlin: Verlag von August Hirschwald, 1920.

ALTITUDE AND HEALTH. By F. F. ROGET, a *Privat Dozent* Professor in the University of Geneva. New York: E. P. Dutton & Co. Pp. xii-186.

THE SURPRISES OF LIFE. By GEORGES CLEMENCEAU. Translated by GRACE HALL. Garden City and New York: Doubleday, Page & Co., 1920. Pp. vi-326.

THIRD INDUSTRIAL DIRECTORY OF PENNSYLVANIA, 1919. Department of Labor and Industry. CLIFFORD B. CONNELLEY, Commissioner. Harrisburg, Pa., 1920. Pp. ii-1212.

THE AMERICAN RED CROSS IN THE GREAT WAR. By HENRY P. DAVISON, Chairman of the War Council of the American Red Cross. Illustrated. New York: The Macmillan Company, 1920. Pp. i-302.

PHYSIOLOGY AND NATIONAL NEEDS. Edited by W. D. HALBURTON, M. D., LL. D., F. R. C. P., F. R. S., Professor of Physiology, King's College, London. New York: E. P. Dutton & Co. Pp. vii-162.

MILITARY PSYCHIATRY IN PEACE AND WAR. By C. STANFORD READ, M. D. (Lond.), Physician Fisherton House Mental Hospital, Salisbury. With Two Charts. London: H. K. Lewis Co., Ltd., 1920.

LEHMANN'S MEDIZINISCHE LEHRBÜCHER. Band I. Erkennung der Geistesstörungen. (Psychiatrische Diagnostik.) Von WILHELM WEYGANDT. München: J. F. Lehmann's Verlag, 1920.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. At the Seventy-fifth Annual Meeting held at Philadelphia, Pa., June 18-20, 1919. Illustrated. Published by the Association, 1919. Pp. vii-600.

SCIENCE AND LIFE. Aberdeen Addresses. By FREDERICK SODDY, M. A., F. R. S., Dr. Lee's Professor of Inorganic and Physical Chemistry, University of Oxford; Late Professor of Chemistry, University of Aberdeen. Illustrated. New York: E. P. Dutton & Co., 1920. Pp. xii-229.

LECTURES ON INDUSTRIAL PSYCHOLOGY. By BERNARD MUSCIO, M. A. (Sydney), M. A. (Conville and Caius College, Cambridge); Late University Demonstrator in Experimental Psychology, Cambridge, etc. Second Edition, Revised. New York: E. P. Dutton & Co., 1920. (London: George Routledge & Sons, Ltd.) Pp. iv-300.

THE MEASUREMENT OF INTELLIGENCE. An Explanation of and a Complete Guide for the Use of the Stanford Revision and Extension of the Binet-Simon Intelligence Scale. By LEWIS M. TERMAN, Professor of Education, Leland Stanford Junior University. Illustrated. New York and Chicago: Houghton Mifflin Company. Pp. xviii-362.

PUBLIC HEALTH AND INSURANCE. American Addresses. By SIR ARTHUR NEWSHOLME, K. C. B., M. D., F. R. C. P., Lecturer on Public Health Administration at the School of Hygiene and Public Health, Johns Hopkins University, Baltimore, Maryland; Late Principal Medical Officer of the Local Government Board, England, etc. Baltimore: The Johns Hopkins Press, 1920. Pp. xiv-269.

ATLAS UND GRUNDRISSE DER BAKTERIOLOGIE UND LEHRBUCH DER SPEZIELLEN BAKTERIOLOGISCHEN DIAGNOSTIK. Von Professor Dr. K. B. LEHMANN, Direktor des Hygienischen Institutes in Würzburg, und Professor Dr. Med. et Phil. R. O. NEUMANN, Direktor des Hygienischen Institutes in Bonn. 6. Auflage. Durch Einen Nachtrag Ergänzt Neudruck der 5. Auflage. Teil 1. Atlas. Teil II. Text. München: J. F. Lehmanns Verlag, 1919.

HYGIENE, DENTAL AND GENERAL. By CLAIR ELSMERE TURNER, Assistant Professor of Biology and Public Health in the Massachusetts Institute of Technology; Assistant Professor of Hygiene in the Tufts College Medical and Dental Schools. With Chapters on Dental Hygiene and Oral Prophylaxis, by WILLIAM RICE, Dean, Tufts College Dental School. Illustrated. St. Louis: C. V. Mosby Company, 1920. Pp. v-400.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Diets for the Ambulant Treatment of Diabetes Mellitus.—Herman O. Mosenthal and Herbert J. Wiener (*American Journal of the Medical Sciences*, July, 1920) says that the measured diets in the modern treatment of diabetes must meet two requirements, the control of the glycosuria and the control of the acidosis. The first is accomplished by regulating the consumption of carbohydrates, the second by adjusting the fat intake. Two sets of diets therefore are necessary, one in which the fats are reduced to a minimum, another in which fats are allowed more liberally, but in limited amounts. The latter is the preferable diet to use when possible, as it is more palatable when continued for a long time. The authors furnish seven tables illustrating the minimal fat diet and the low fat diet. Table I gives the minimal fat, starch free diet; Table II the meat and fish portions for use with the minimal fat diet; Table III a list of vegetables that may be used in both forms of diet; Table IV the low fat, starch free diet; Table V the meat and fish portions for use with this diet; Table VI the approximate quantities of protein, fat and carbohydrate in the minimal fat, starch free diet when round steak or bluefish are used as meat or fish; and Table VII the approximate quantities of protein, fat and carbohydrate in the low fat, starch free diet when roast beef, steak, or flounder are used as meat or fish.

Modern Individualized Dietary Treatment in Diabetes.—Marius Lauritzen (*American Journal of the Medical Sciences*, July, 1920) maintains that no single dietary scheme suits the different forms and stages of this disease, and that each patient has to be examined carefully and treated with the diet that qualitatively and quantitatively suits him at the time. In a mild case he gives the patient mixed food, or the diet prescribed by the practitioner who sent him, and makes quantitative examinations for blood sugar, urinary sugar, nitrogen and ammonia in the urine, acetone, diacetic acid, albumin, etc. The patient is then given a test diet for two or three days consisting of 150 grams of roast meat, four eggs, eighty grams of butter, fifty grams of cheese, three hundred grams of vegetables with two to five per cent. of carbohydrates, one hundred grams of compôte of rhubarb, two hundred grams of broth, one hundred grams of cream, one hundred grams of bread, one third bottle of claret, five hundred grams of tea, five hundred grams of coffee, and five hundred grams of soda water. This diet contains one hundred and four grams of protein, one hundred and forty grams of fat, seventy-two grams of carbohydrate, eighteen grams of alcohol, total 2,151 calories. In some mild cases the urine will be sugar free in two or three days. If this is not the case, or if the percentage of blood sugar remains above normal, a vegetable diet is prescribed for one day, and then an animal diet, which is like the test diet but without cream, bread, according to the nature of the case, being replaced by sixty to one hundred and twenty grams of gluten bread or

left out altogether, or changed for vegetables very poor in carbohydrates. The diet fixed in this way is kept up for months.

In uncomplicated cases of moderate severity one of the following methods of treatment may be employed.

1. The treatment described above, with strict vegetable diet for several days, may be applied until the attainment of the desired result, when a slow passage to mixed diet poorer in proteins than the first diet may be made.
2. Instead of a strict vegetable diet, fasting may be used as advised by Allen or Cantani, followed by a slow passage to a diet poor in protein.
3. One may rest content with intercalating one vegetable day at a time and then pass to a diet poorer in protein intercalating, if needed, another vegetable day, after which the ration of protein is further restricted, until blood sugar and urine are normal.
4. If the case is one in which ketonuria is likely to develop, as in children and in very young people, Lauritzen generally has recourse to Von Noorden's oat cure, with the rations of oatmeal and butter, kneaded in water to remove fatty acids, that are suited to each individual case; after the concluding vegetable days he slowly passes to strict animal diet with vegetables. If diaceturia is troublesome, small doses of alkalis may be used. In severe cases with acidosis of moderate severity, as a rule treatment according to method No. 3 is applied, with reduction of the protein, especially meat and food containing casein. Both protein and carbohydrate are gradually restricted and replaced by green vegetables until the attainment of aglycosuria and the lowest percentage of blood sugar possible.

If the immediate attainment of sugar freedom is wanted, vegetable treatment or fasting with confinement to bed is used. When aglycosuria and hypoglycemia are not attained by method No. 3, he tries Von Noorden's oatmeal treatment. If one of these methods succeeds in rendering urine and blood normal and removing ketonuria, diet poor in protein, plus vegetables poor in carbohydrate with washed out butter, or with olive oil, vinegar and other spices, and for drinks soda water, tea, coffee, and brandy should be continued as long as possible. In the severest cases with heavy acidosis treatment is more difficult and, as a rule, we have obstipation and dyspepsia to contend with. Confinement to bed for a considerable period is necessary. The acidosis will diminish through vegetable treatment or fasting with or without subsequent oatmeal treatment. Alkalis should be used. The diet in the aftertreatment must contain very small quantities of protein, vegetable protein and protein of hen's eggs are tolerated here better than any other. Carbohydrate must be derived from vegetables and fruits containing little. Avoid milk and cream. Alcohol is almost indispensable in large doses of claret, hock, sugar free champagne, brandy or whiskey according to the patient's liking.

The Treatment of Chronic Fatigue.—John Bryant (*Boston Medical and Surgical Journal*, June 17, 1920) says that the world is full of persons, mostly chronic invalids, who react excessively to sensory stimuli of both mental and physical origin. One obvious ultimate result of this continued overreaction to sensory stimuli is chronic fatigue, and the patient will not recover until this is relieved. In order to relieve the chronic fatigue, its cause must be attacked. Diet and exercise, properly used, are valuable factors in decreasing overreaction to sensory stimuli and promoting a return to health of the chronic invalid. The foremost essential in the regulation of the diet is the temporary elimination of meat and fish, and the thorough cooking and careful serving of all foods allowed. A direct method of raising the action of the control mechanism toward normal is the employment of a special type of physical exercise which has for its immediate object the sharpening of muscle sense perception in relation to balance and physical poise.

The Treatment of Thyroid and Other Endocrine Disturbances as Viewed by the Internist.—John A. Lichty (*American Journal of the Medical Sciences*, June, 1920) thus summarizes his paper: 1. Exophthalmic goitre or hyperthyroidism from other causes should be recognized early and treated promptly. 2. The earlier it is recognized, the more likely is medical treatment to be sufficient and to give permanent results. 3. The neglected cases or cases having definite pathology besides are likely to require surgery or röntgen ray, or both. In this is included radium. 4. The röntgen ray treatment of the enlarged thyroid presents most attractive advantages, but the indications for its use do not seem definite yet, and the results are not so certain. 5. In hyperthyroidism the röntgenologist and the surgeon at best can only break through a vicious circle for which the internist may or may not have been responsible.

Tissue Sparing Amputations of the Foot.—Savariaud (*Presse médicale*, February 7, 1920) notes that, in practice, it is seldom possible to perform a classical Lisfranc or Chopart amputation owing to lack of a plantar flap. Better than to resort to a Syme operation or some osteoplastic procedure involving the heel, is, if the disease is confined to the border of the foot and the tissues immediately adjacent, to bring over the integument from the opposite side. According to existing conditions, then, a flap is made on the inner or outer side of the foot with all the normal portion—usually a half—of the dorsoplantar integument. By slight twisting the flap is brought opposite to the cut bone surface and sutured. A good bearing surface is thus obtained upon the plantar aspect, and at the same time enough bone can be saved to reproduce a Lisfranc operation, though a flap only one half as large is required. The author employed this procedure in four cases, with excellent results. One patient had been subjected to trauma, another had a sarcoma of the muscles of the great toe, and two had tuberculosis of the inner tarsometatarsal bone tissues with sinus formation. The latter condition constitutes the largest field for the operation described.

The Cure of Chancroids with the High Frequency Current.—W. C. Kessler (*Urologic and Cutaneous Review*, May, 1920) emphasizes certain points in the technic: There is more danger of too little cauterization than too much; thorough cleansing at the time the sore is fulgurated must not be neglected; especial care must be exercised in carrying the spark well down into every fissure and undermined edge of the sore; the application should extend over the edge of the sore about one sixteenth inch into the apparently healthy area; the current is not turned off until every crack and crevice has been thoroughly treated and the surface of the sore has been turned to a dark greenish gray; the surface of the sore is then covered with a thick moist dressing of a two per cent. solution of boric acid; tap water often answers just as well. This method has produced excellent results. Treatment is given every two days.

Injection of Turpentine Oil in the Treatment of Lethargic Encephalitis.—A. Netter (*Bulletin de l'Académie de médecine*, April 6, 1920) recommends injection of oil of turpentine to induce a fixation abscess in all cases of lethargic encephalitis, as soon as the diagnosis has been made. Out of nineteen cases in which this measure was carried out and in which an abscess formed so that it could be incised, all but two patients recovered, and these two deaths were both in pregnant women, in whom lethargic encephalitis is known to be particularly dangerous. Recovery was especially rapid among the patients in whom the oil injection and the opening of the abscess were carried out early. This indicates that the treatment should be applied not only in the more severe cases but in all patients with this disease. The diagnosis of the latter may now be made quite early, thanks to the procedure of investigating the "electric" muscular contractions recently described by Sicard. Testing for the amount of glucose in the cerebrospinal fluid is likewise of service in early diagnosis.

Differentiation of Structures by the X Ray.—Gustav Kolischer and R. A. Arens (*Urologic and Cutaneous Review*, May, 1920) consider two problems: 1, How to accomplish the elimination of the secondary rays in order to avoid blurring of the picture, and 2, how to establish a graded relation between the pictorial density of the organs and certain pathologic changes.

The authors use an aluminum filter of two millimetre thickness, in order to prevent the interference of the secondary radiation with the clearness of the picture taken of an organ. This as a rule is sufficient to bring out the contours of the organ in question very clearly.

In order to illustrate the possibilities of this proposition, three observations are noted. In the first, in a case of sarcoma of the epididymis, the outlines of the tumor in contrast with the shadow of the testis were not to be seen distinctly on the röntgenogram until a picture with interpolation of a three millimetre filter was taken. In a case of unilateral proliferating tuberculosis of a kidney and in cases of kidney stone, the interpolation of the filter gave a much better and more distinct picture.

The President, Sir HUMPHRY D. ROLLESTON, K.C.B.,
M.D., F.R.C.P., in the Chair.

(Continued from page 432)

Diagnosis of Nervous Disorders of the Stomach and Intestines.—Dr. ARTHUR F. HURST, physician and neurologist to Guy's Hospital, pointed out that an attempt must be made to gain a clear conception of what was meant by certain terms, such as functional neurosis, psychoneurosis, neurasthenia, and hysteria. A functional disorder was one which did not depend upon organic change; it might be either biochemical or nervous in origin. Functional disorders of nervous origin were of two kinds: the neuroses, which were independent of mental processes, whether conscious or subconscious, and the psychoneuroses, which had a psychological cause. This distinction was of fundamental importance, as the psychoneuroses alone were amenable to psychotherapy. Neurasthenia had generally been classified as a neurosis, but it really depended upon definite though evanescent organic changes in the central nervous system and in the suprarenal and possibly endocrine glands, resulting from mental and physical exhaustion and chronic intoxications. It was, therefore, an organic and not a functional disorder. However, the relation of neurasthenia to the nervous disorders of digestion required discussion.

The psychoneuroses could be classified under the headings of hysteria and psychasthenia. Before the war Hurst would have classed the tics separately, but he was not convinced that they were really hysterical. By hysteria was meant a condition in which symptoms were present which had been produced by suggestion and were curable by psychotherapy. During the war his fellow workers and he gathered together a great deal of evidence to show that in the absence of gross hysterical manifestations there was no underlying condition to which the name of hysteria could be given. They had confirmed Babinski's observations that Charcot's physical stigmata were invariably a result of suggestion on the part of the observer, and, what was more important, they were firmly convinced that although an abnormal degree of suggestibility predisposed to hysteria, it was not essential and that hysteria might occur in individuals with a perfectly normal mental makeup. When this was once realized, it became clear that absence of the mental characteristics which lead to an individual being labelled as neurotic did not in any way exclude the possibility of the digestive or other disorder from which he was suffering being hysterical, any more than it could be assumed that symptoms in a neurotic girl were not due to

organic disease. It followed that a diagnosis could only be made from the nature of the symptoms and the results of physical and laboratory methods of examination.

Hurst pointed out that the traditional description of the nervous disorders of digestion depended upon false ideas of physiology and anatomy. It was, for example, assumed that a certain degree of tone and a certain activity of peristalsis were normal and that a normal stomach secreted juice of a certain strength. Any divergence from these standards, which were as a matter of fact often vague, was regarded as evidence of disordered function. Such a condition as atonic dyspepsia, due to atonic dilatation of the stomach caused by deficient tone, associated with deficient peristalsis and secretion, and acid dyspepsia due to hypersecretion were described, while the more scientific writer spoke of hypochlorhydria and hyperchlorhydria as clinical entities. In addition to the motor and secretory neuroses a sensory neurosis was recognized in which indigestion was supposed to result from hyperesthesia of the gastric mucous membrane.

Hurst's own investigations, which had been confirmed by numerous radiographers both in England and abroad, and the recent chemical investigations by fractional test meals carried out by Reh fuss and Crohn in America and Ryle and Bennett at Guy's Hospital, had shown that such great variations occur in the muscular tone, peristalsis, and secretory activity of the stomach in normal individuals that it might well be doubted whether what was generally regarded as atonic dilatation, hyperchlorhydria and hypochlorhydria did not really fall within the normal limits. This remained true even when the diagnosis was supported by an x ray examination and gastric analysis. Hurst had seen so many doctors who believed patients had atonic dilatation of the stomach, but found with the x ray that they had hypertonic stomachs, and he had seen so many many in which the symptoms pointed to hyperchlorhydria but actually achylia was present, that he was quite certain that it was utterly impossible to form a reliable estimate of the muscular or secretory activity of the stomach from a consideration of the symptoms alone. The investigations he carried out with several of the students of Guy's Hospital some years ago proved, moreover, that the theory of gastric hyperesthesia had no basis in fact, as the mucous membrane of the stomach both in health and disease was entirely insensitive to tactile, thermal, and painful stimuli and to hydrochloric acid up to the maximum strength in which it could conceivably be present in the gastric juice. The discovery of variations from the average normal tone peristalsis and secretion in individuals with digestive symptoms was, therefore, no evidence that these variations were in any way responsible for the symptoms.

The atonic dilatation and hyosecretion which were supposed to be the cause of dyspepsia of the exhausted neurasthenia as a rule existed only in the imagination, as there was not the smallest evidence to show that true neurasthenia in any way affected the motor or secretory functions of the stomach. He could well believe that an exhausted individual who happened to have a stomach the tone, peristalsis and secretion of which were below the average, would be more likely to suffer from indigestion than a man with a normal stomach. His condition might be correctly described as neurasthenic dyspepsia and he might benefit from treatment directed to increase the motor and secretory activity of his stomach, but it must be remembered that the neurasthenia was not the cause of the deficient tone and secretion, and that in the absence of the neurasthenia there would be no digestive symptoms although the deficient tone and secretion would still be present. Exhaustion might be the exciting cause of a different group of gastric symptoms in a man whose stomach was of the hypertonic hypersecretory type, and these symptoms might be the herald of an attack of duodenal ulcer. But the hypertonus and hyperchlorhydria were congenital and not caused by the exhaustion or the duodenal ulcer; they simply predispose to a certain form of indigestion—the acid dyspepsia or hyperchlorhydria of the textbooks which occurred as a result of various conditions, one of which was exhaustion. Hurst believed there was little justification for retaining such terms as atonic dilatation of the stomach, hyperchlorhydria, hypochlorhydria, atonic and acid dyspepsia, as descriptions of clinical conditions. We could separate two varieties of neurasthenic dyspepsia, which, however, could be recognized with certainty only by the aid of the x rays and gastric analysis; the atonic, occurring in an individual with a stomach with less than the average tone and secretion, and the hypertonic, occurring in one with a stomach with more than the average tone and secretion.

It was comparatively rare for a patient to consult a doctor on account of constipation without having already attempted to cure himself with aperients. But no accurate diagnosis could be made until it had been ascertained whether the patient was really constipated. In Dr. Hurst's experience the symptoms generally ascribed to autointoxication caused by intestinal stasis were really produced by purgatives. They led to the absorption of an excess of toxic material, partly by hastening the half digested contents of the small intestine into the cecum where fermentation and putrefaction were consequently increased, and partly by causing the contents of the transverse, descending and pelvic colon to be fluid instead of solid, so that absorption of toxins took place in the cecum and ascending colon alone. The patient should be instructed to see what happened if no drugs were taken for a week, an effort being made to open the bowels each morning. In most cases he quickly lost his abdominal pain and his so-called toxic symptoms. The bowels were often opened daily, in which case a diagnosis of hysterical pseudoconstipation could be made—hysterical because the patient had suggested to himself as a

result of faulty education combined with the reading of pernicious advertisements that he was constipated and required aperients to keep him well, whereas a little psychotherapy in the form of explanation of the physiology of his bowels and the origin of his symptoms, and persuasion to try to open his bowels each morning without artificial help, resulted in a cure. In many cases, however, the patient did not succeed in opening his bowels, although he might feel more comfortable than when he was taking drugs. A further abdominal and rectal examination should then be made. If no sign of organic disease was present and if, as was generally the case, no accumulation was felt in the abdomen, the rectum would be found filled with feces which were in some cases stony hard but in others quite soft, proving that there was no delay in the passage through the intestines. In spite of this the patient had no desire to open his bowels, although a normal individual would feel an urgent call to defecation under the conditions. In 1908 he called this condition of inefficient defecation dyschezia to distinguish it from true intestinal stasis, in which there was a delay in the colon. The majority of cases of dyschezia, which was the commonest form of severe constipation, were of nervous origin. They were caused by neglect to respond to the call to defecate owing to laziness, insanitary conditions of toilets, or false modesty.

The rectum gradually dilated, so that an increasing quantity of feces was needed to produce the internal pressure required to give the sensation of fullness which was the natural call to defecation and finally the sensation was lost completely. But the patient was still capable of emptying his rectum if he tried. He had, however, convinced himself that he could not get his bowels open unless he took enemata or such enormous doses of aperient that the fluid feces practically acted as enemata. He thus suggested to himself that his rectum was powerless to act by itself, true hysterical dyschezia being thus produced. In many cases no treatment was required beyond explaining to the patient the nature and cause of his condition and persuading him to make an effort to empty his rectum, which he must realize was quite capable of doing its work, but occasionally it was also necessary to reeducate his rectum with graduated enemata. In severe cases it was advisable to examine the intestinal functions with the x rays, a barium meal being given after the patient had discontinued taking his aperients.

Dr. Hurst said that the time table he gave ten years ago for the passage of food along the alimentary canal was nothing more than the average taken from numerous records obtained with the x rays, but it had unfortunately often been regarded as representing the normal standard, the slightest variations from which indicated the presence of intestinal stasis. The fallacy of this had been pointed out frequently, as the normal limits were very wide, but he still often saw patients who had been advised to submit themselves to colectomy or other drastic treatment as a result of an x ray examination which showed a somewhat slow passage, which was, however, well within the normal. He therefore thought it necessary once again to

describe briefly the evidence required in order to diagnose stasis in different parts of the intestinal tract. Ileac stasis should only be diagnosed if no trace of barium had reached the cecum six hours after the opaque meal, or if a considerable quantity of barium containing chyme was still in the end of the ileum nine hours after the meal, if the stomach was known to have emptied itself in three hours. If most of the barium was still in the cecum and ascending colon at the end of twenty-four hours, they were the seat of stasis, even if a little had passed to the more distant parts of the colon, but a faint shadow of the cecum was often visible in normal individuals even three days after the meal. If the splenic flexure was reached in twenty-four hours and the greater part of the barium was in the transverse colon at the end of forty-eight hours, there must be stasis in the transverse colon. Lastly, if at the end of twenty-four hours the greater part of the barium had collected in the pelvic colon or rectum or both, and in spite of this no desire to open the bowels was felt, dyschezia could be diagnosed. Apart from dyschezia the only common form of constipation of nervous origin was that resulting from anorexia. Anorexia was a common symptom of both neurasthenia and psychasthenia, and the deficient stimulation of the intestine which it caused generally led to a slow passage through the entire colon. Intestinal activity was also likely to be inhibited by depressing emotions in psychasthenia. There was, however, no evidence to show that the nerve exhaustion of neurasthenia had any influence on the bowels. Hurst was convinced that no such thing as atonic constipation existed, for tone and peristalsis were independent functions; and whereas deficient peristalsis was a common cause of constipation, the x rays had proved that atony of the colon was a rare condition, generally organic in origin and not necessarily associated with any disturbance in peristalsis.

SECTION IN TROPICAL MEDICINE.

The President, Professor G. H. F. NUTTALL, M. D., F. R. S.,
in the Chair.

Dietetic Deficiency and Endocrine Activity.—Lieut.-Colonel ROBERT McCARRISON, M. D., D. Sc., LL.D., F. R. C. P., of the Indian Medical Service, pointed out that the endocrine organs, regulators of metabolism, were profoundly influenced by dietetic defects. This fact had been demonstrated by experimentation on pigeons, guineapigs, and monkeys. Animals of these species were fed on six classes of deficient dietaries. The first was deficient in all three classes of vitamins and in suitable protein, and was disproportionately rich in carbohydrates; the second was deficient in B and C vitamins and disproportionately rich in carbohydrates and fats; the third was deficient in B vitamin and disproportionately rich in carbohydrates and fats; the fourth was deficient in A and B vitamins; the fifth in B vitamin only; the sixth in C vitamin only. The effects of these dietaries on the endocrine organs was attributable to three factors operating in varying combinations: 1, Deficiency of vitamins; 2, imperfect balance of the food with respect to proximate principles; 3, the fortuitous

occurrence of pathogenic agents in the body. The first two factors came into operation when the first three dietaries were used; they were aided in a proportion of cases by the third factor. The first factor was chiefly concerned in producing the results when the last three dietaries were used. It also was aided in a proportion of cases by the third factor. McCarrison summed up as follows:

1. Dietetic deficiency had a profound influence on endocrine activity.
2. All endocrine organs, with the adrenal glands and the pituitary body, underwent a greater or less degree of atrophy and depreciation of functional capacity as a result of dietetic deficiencies.
3. The adrenal glands and in males the pituitary body enlarged in consequence of dietetic defects; the former greatly, the latter slightly.
4. The adrenals were the most susceptible of all endocrine structures to dietetic defects.
5. The character of the adrenal enlargement varied with the character of the dietetic deficiency.
6. The adrenalin content of the enlarged adrenals varied with the character of the dietetic defect. It was in excess of normal when the food was deficient in vitamins, in proteins, and disproportionately rich in starch; it was below normal when the diet was scorbutic and also when concurrent infections were associated with dietetic defects.
7. Edema was invariably associated with massive enlargement of the adrenal glands in pigeons fed on autoclaved rice, but massive enlargement of the adrenals was not invariably associated with edema. This association bore an intimate relationship to the adrenalin content of the enlarged organs; when the content was high edema occurred in eighty-six per cent. of cases; when the content was low edema did not occur.
8. Fresh butter contained some substance which tended to protect against edema. This substance was not present in a coconut oil.
9. The hypothetical "antiedema substance in butter had a pronounced influence over the adrenal glands. It appeared to exert its protective action against edema by maintaining their adrenalin content at a low level.
10. Butter varied in its capacity to protect against edema. This variation was dependent on the quality of the cow's food; butter was richer in antiedema substance when the cows were fed on green fodder than when they were fed on dry fodder.

In a paper on the pathogenesis of deficiency disease published some time ago McCarrison suggested that edema was initiated by increased intracapillary pressure consequent on hyperadrenalinemia. More extended experience had caused him to alter his opinion. Recent work on the effects of adrenalin did not support this suggestion. It seemed more probable that an excess of adrenalin might reach the kidneys direct and interfere with the normal excretion of urine, thus favoring the retention of fluid in the tissues. A number of closely correlated facts pointed in this direction. Thus the adrenals were enlarged in human beri beri and their adrenalin content was high, the urinary output in human beri beri is small, although in general no disease of the kidneys was present; excess

of adrenalin introduced into the venous circulation inhibited the flow of urine (Gunning) and caused retention of sodium chloride in the tissues (Bulche and Weiss); a channel of communication existed between the adrenal glands and the kidneys, whereby the products of the glands might reach the kidneys without either dilution or oxidation in the general circulation, (Gow). finally a diminution of the flow of urine could be produced by the direct action of adrenalin reaching the kidneys by this route (Gow). Adrenalin thus appeared to control the excretion of urine; this being so, it was of great importance to be aware of the fact that adrenalin was in its turn controlled by the quality of the food. Other factors in addition to impaired excretion no doubt played their part in the causation of edema—impairment of endothelial function with associated alterations in vascular permeability, impaired metabolism of proteins and lipoids, and chemical changes in the tissues themselves, all of which were consequences of the disturbed endocrine function and of the disturbed metabolism which was the outcome of vitamine deprivation and malnutrition.

SECTION IN PATHOLOGY AND BACTERIOLOGY

The President, Professor J. LORRAIN SMITH, M. D., F. R. S.,
in the Chair.

Present Position of Cancer Research.—Dr. J. A. MURRAY, Director of the Imperial Cancer Research Fund, said that attention should be drawn to the bearing of the results of experimental work on the important statistical character of cancer, and its increasing frequency with advancing age in man and animals. It was not easy to say to what extent this peculiar age incidence was a consequence of the chronicity of the forms of irritation which most constantly led to the development of cancer and how far senile cellular changes were a necessary antecedent. The results of the culture of normal tissues *in vitro* showing practically unlimited powers of growth under suitable conditions would appear to relegate the senile failure of growth to a position of secondary consequence of accidental cell damage inseparable from the chances of life. If this were so, then the age incidence of cancer could be regarded as a consequence of the relative inefficiency of most of the forms of irritation associated with the origin of cancer in producing the disease.

In support of this view it could be noted that Dr. L. J. Dublin recorded a higher evidence of cancer in the experience of a New York insurance company among industrial policyholders than among those in easier social circumstances. The former were of necessity more exposed to various forms of chronic irritation than the latter. Fibiger had developed the same argument in reply to the objections raised to the cancerous nature of the growths in rats' stomachs, namely that they were not necessarily associated with old age. He claimed that the spiroptera infection was so potent a cause of the disease that the long duration necessary in other forms of irritation was not required.

(To be concluded)

Letters to the Editors.

INTERNATIONAL ASSOCIATION OF PNEUMOTHORAX ARTIFICIALIS.

NEW YORK, August 31, 1920.

To the Editor:

I have been requested by Professor Carpi, of Lugano, Switzerland, the General Secretary of the International Association of Pneumothorax Artificialis, to translate the following circular letter from the French which he had recently sent me, and to cause it to be published in as many of the American medical journals as will be willing to give it space. May I ask you to extend to it the hospitality of your esteemed paper, and believe me

Very truly yours,

S. ADOLPHUS KNOPF.

The International Association of Pneumothorax Artificialis, the work of which was paralyzed during the long war, desires to resume its activity by inviting all former members of the association to renew their subscription and all other physicians interested in artificial pneumothorax to send their names and addresses to Professor Umberto Carpi, Lugano, Switzerland, and to become members.

The purpose of the association is to spread all practical and scientific information concerning artificial pneumothorax. Although induced pneumothorax for therapeutic purposes has become remarkably prevalent it has remained a procedure applied only by physicians specially trained and experienced in this operation. For the convenience of the patients who may be obliged to change their residences, to know the names and addresses of physicians who practice artificial pneumothorax is of great value, in order that the patient may continue the treatment by periodic refilling. A complete list of physicians practicing artificial pneumothorax will be published with the scientific journal known as *Pneumothorax Therapeutique* for 1920-1921, edited by Carlo Forlanini. This list will be sent to all the members and to the most important medical societies, medical academies, and similar institutions of the different countries. In the journal will be enumerated and discussed all the world's literature on pneumothorax. The association will continue its labors under the policy indicated by the illustrious master and creator of artificial pneumothorax therapy. As soon as the finances of the society will permit the renewal of the publication, the editor will put himself in communication with the editors of such medical journals of other countries as are publishing articles on artificial pneumothorax. For the present these are *die Sonderhefte des Tuberkulose Centralblattes ueber Lungenkollapstherapie* and the monographs in the journal *La Tuberculosi*, Rome.

The subscription price of five francs should be addressed to the General Secretary, Prof. U. Carpi, Lugano. The subscriber is entitled to receive the journal with the list of names. Those who desire to receive the monographs of the journals indicated should make a request for them to the General Secretary, who also has an international exchange office for all publications appertaining to artificial pneumothorax. Summaries in English, French and German on any topic relating to artificial pneumothorax will be gratefully received and published.

PROF. U. CARPI, General Secretary.

PERSISTENT VOLUNTARY MUTISM.*

BY ALFRED GORDON, M. D.,
Philadelphia.

Mutism is a form of speech disturbance which may be encountered in a large variety of conditions. Hysteria is the affection in which mutism is most frequently found. In the works of older writers facts are recorded showing sudden recovery from mutism; they all have reference to cases of hysteria. In this affection the condition may develop suddenly after an emotional disturbance or gradually after a period of aphonia, when the patient is still able to converse but in a low voice. Occasionally traumatism or an infectious disease is likely to be the cause of mutism.

Among other causative factors of mutism may be mentioned abulic inhibition in psychasthenia and the psychoses. Mutism is frequently observed in the insane. It is common to see in them an obstinate silence extending over months and years. The depressive cases usually present a mutism of long duration together with absolute immobility. In the cases of negativism, such as is observed in dementia præcox, mutism may be one of the negativistic manifestations. In a patient under the writer's observation, after the birth of her first child and after a period of slight confusion accompanied by mild delirium, a state of resistiveness developed which soon invaded the faculty of speech and mutism followed. Not only words but even sounds are never emitted by the patient. She is absolutely silent but at times movements of the lips are observable as if she was making an effort to reply to questions asked. The mutism has been in existence for nine weeks and there is no indication of a prompt return of her voice.

That organic cerebral lesions are likely to produce aphasic manifestations and complete mutism is too obvious to dwell upon. In the recent war traumatic cases have been observed in which the individuals lost consciousness. After the return of consciousness amnesia or deafness was noticed and when the injured attempted to speak they failed. As there was no intervallary period and the loss of speech was immediate, there can be no hesitation as to the hysterical character of their mutism. Emotion probably played a preponderant rôle.

Mutism in children, apart from the psychoses, is rare. The following case presents an example of

mutism occurring in a child of thirteen previously free from morbid phenomena. It also presents a group of phenomena in which the mutism developed concurrently with profound changes of personality. The mutism is persistent in spite of the fact that the patient is fully conscious of it.

CASE.—Boy, A. S., thirteen years of age, heretofore with a school record of average intelligence, happened to read a book containing a story of a man who gradually lost his speech. Soon his parents noticed that the boy talked very little, only what he was obliged to say. Rapidly he ceased to speak altogether. Not only his speech but his voice could not be heard in the house. During a period of six months the condition remained unaltered.

Presently he was totally mute. No word or sound was ever uttered by him. Occasionally he could be heard laughing in his room; he did it only when nobody was around him and the sounds reminded one of those uttered by a wild animal—they did not resemble those coming from a human larynx. They were brief, unusually loud and rough—not continuous but sharply interrupted. He indulged in such laughing without the least provocation and, as mentioned before, exceptionally.

All attempts to make him speak utterly failed. He fully understood when he was spoken to and was always willing to give replies to questions in writing. Asked why he did not speak, he shrugged his shoulders and wrote down, "I don't know." Asked whether he would like to speak, he replied, "No." Asked whether he would ever speak again he replied in writing, "Yes," but when asked to name the date he shrugged his shoulders and wrote down, "I don't know." Asked again whether it would be more than a year, he wrote, "Yes," but when asked, "Will it be less than two years?" he replied, "I don't know." To all efforts to make him admit the necessity of communicating with fellow beings by speech he invariably persisted in shrugging his shoulders and in writing, "I don't know." He spent his time in his room in reading or writing. He read anything that he could lay his hands on but he was especially fond of serious subjects concerning industry and development of the cities in the United States. At my request, for the purpose of testing his ability of fully grasping the essential features of a serious article, the patient wrote down a résumé of two papers published in the *Saturday Evening Post*. It was presented by him in a fairly logical manner and in fairly correct English.

* Read before the Philadelphia Psychiatric Society, May 14, 1920.

He was so eager to spend his time reading that all the money he succeeded in getting from his parents he used for purchasing magazines and newspapers. In buying the latter he did not speak but rushed to the stand, handed over the money, picked up the article purchased, and left at once. All his acts, including walking and eating, were done in an abrupt and jerky way. When he was through eating he rushed upstairs with great speed and locked himself in his room, went to bed and abandoned himself to his favorite occupation, reading. Hastiness and rapidity were seen even in reading; he devoured the books, according to his parents, and would read two or three books in a day. Unusual rapidity was noticed in eating. He never allowed anyone to wait on him. Should his mother put some food on his plate, he would not eat it; he must help himself and before doing so he wiped the plate two or three times to make sure of its thorough cleanliness though he would pile on it indiscriminately anything he could get hold of to eat. Occasionally he would sit at the table with his parents and the other children, and then no one could wait on him: he reached for the food before anyone else had time to sit down, and as soon as he had finished he rushed upstairs to his room. Not only did he eat rapidly but he ate abundantly and ravenously, more than anyone else, and more than he ever did at the time before the mutism had developed. As the parents said, he did not eat like a human being but like a wild animal.

In his room he kept the windows and door hermetically closed, placing paper and rags in each crevice and opening that he could find. He smoked cigarettes only in his room. The air was suffocating when one entered and the only time that ventilation was possible was when he was out on his errands of buying a paper. When he was in the room he would never permit a window or door to be opened and when he observed that the paper or rags were removed from under the door he became excited and immediately replaced them; with violent gestures and movements of his hands he expressed his dissatisfaction and threatened bodily injury. While in the room he seldom sat on a chair, but was always found in bed.

He was not particular about his personal appearance, although he was always careful in having his collar and necktie on when he expected me to visit him. He slept in his drawers but would not have underwear on during the day and in the coldest days of winter he would go out without undergarments. From a former careful and neat boy he became slovenly, as he did not care how he appeared before strangers on the street and before the magazine dealers whom he saw daily when buying his papers. Questioned on this subject he wrote that he did not know why he changed at all. When asked why he did not appear well dressed he gave the reason, "Since I will not speak to people," as his written reply.

Beside the newspaper stand, the only other place he liked to go to was the cinema. Among the pictures he preferred those which dealt with strong scenes, stories of the woods, shooting, and attacking. He did not care for sentimental stories.

In his relations with members of the family it was interesting to notice a pronounced want of affection. In him there developed a particular dislike and even an open antagonism toward his twin sister; at times he showed hatred and not infrequently he attacked her. Interrogated on the subject he wrote that he did not believe she was his sister and that he did not wish to have anything to do with her; she could not possibly be his twin, he said.

He did not show any trace of affection toward the other brothers and sisters; he never went near them, refused to spend any time with them and always declined their invitation to go to the cinema or to play together. He never looked at them. If they happened to be in the room when he entered, he immediately left. Toward his parents he was totally indifferent. He would never carry out an order given by them. He was afraid of his father because the latter threatened bodily punishment. The supplications of his mother were totally ignored by him and were of no avail as to the correction of his changed habits or with regard to his mutism. It is well to remember that prior to this period he was fond of his relatives and showed toward them the affection of the average normal child. Presently he avoided them, and was not concerned at all if an illness occurred in the house or if an accident occurred to anyone in the family. The open enmity and antagonism to his twin sister, the indifference to his other sisters and brothers, total lack of consideration for his mother, and absolute want of affection for his father have been the most striking features since the condition developed.

His innermost desire to be detached from his family was shown in a letter which he wrote to some distant relatives at the pressing and repeated insistence of his mother. After expressing his pleasure at their safe arrival and wishing them a happy life in the future, he terminated the epistle by saying, "Regards to all," signing, "Anna, David, and the whole family except myself."

The boy's previous medical history presented no striking peculiarity as far as could be ascertained from his parents. However, enuresis had been present since infancy; he still continued wetting his bed every night. He was born at term, commenced to speak and walk at a normal age, never met with an accident and never sustained an injury. He was considered a strong and healthy boy, and he went to school and made progress as the average boy. Nevertheless he was not fond of play, preferred to stay home and was selfconscious and timid. He was very sensitive to remarks about his personality or to any offense. He was shy in the presence of strangers. He did not show a penchant for any special play or study or other activity. He exhibited no peculiarities in his general behavior or special tendencies. There were no vicious or defective habits.

The physical examination of the boy gave negative results. Station, gait, motor and sensory apparatus, and pupillary reactions were all normal. Hysterical stigmata were absent. The cardiorespiratory apparatus was normal. Larynx, pharynx, vocal cords, showed no lesions. The family history was

negative as far as constitutional diseases were concerned. The parents were of average intelligence and the other children presented the average type of apparently normal children. Although serological tests were not made, nevertheless there were no clinical indications whatsoever to suspect an underlying luetic basis in the parents or in the physical characteristics of the children.

To sum up, we were dealing with a young individual who, along with normal features in the intellectual sphere, presented certain abnormalities in the field of judgment and in the domain of his affective faculties. The abnormal manifestation of absolute mutism developed rapidly after reading a story on mutism. No power of persuasion or argumentation succeeded in breaking the disorder. One witnesses here not only the development of a speech and voice disorder, but a decided change in the entire personality. On one hand the boy's attitude toward his parents and nearest relatives became distinctly altered; not only did he disregard their advice or orders, but he lost all sense of obligation, of obedience, of respect, of affection, and there even developed a sense of enmity and hatred toward one of them. Moreover his behavior, his manner, his failure of comprehending the discussion of his mutism, his contradictions in replying to questions concerning the disorder, all denote a profound change in a boy who previously presented a type of individual of average intelligence.

Although the mutism was the most conspicuous morbid phenomenon in this case, nevertheless it was not an isolated manifestation. It was associated with a number of other abnormal symptoms. The latter were not the result of and are not focused around the former. They were manifestations of a different order. The mutism was evidently due to an inhibitory functional paralysis of cerebral nervous centres which controlled speech and emission of sounds, affecting not only the highest cortical levels but also the unconscious mechanisms depending upon the middle levels (Grasset) as well as the muscles themselves connected with speech and sound. May we not be dealing here with a paralysis due to an inhibition or to exhaustion produced by excessive stimulation of the nervous system, and in this particular case through intensive reading of a story concerning a man who ceased to speak? Further analysis shows that only the motor element of speech was involved. Since the sensory speech was intact (he understood spoken or written words), the motor centre of speech was evidently separated from the ideative centres and consequently from the remaining cortex. The function of the associative fibres going from the entire cortex to the motor speech centre was disturbed or interrupted.

The mechanism of the interruption of function in this case is apparently intimately associated with the deep impression caused by the reading about the loss of speech. A question arises: Are we dealing here with a case similar to those observed after deep emotions? A multitude of cases of mutism have been reported in the last war following explosions in the vicinity but without material injury to the individuals. That in civil life strong emotions

may be followed by aphonia has been known from time immemorial. Hysterical aphonia and hysterical mutism are well known conditions. In the present case the patient was totally free from mental stigmata of the great neuroses. The emotional element was equally not of the character usually observed in hysterical aphonia or mutism as far as the suddenness of their appearance was concerned. On the other hand other symptoms suggest the possibility of hysterical mutism in that there was no trace of word deafness or word blindness; it was a motor aphasia in the extreme degree. Malingering is also not to be considered by virtue of the fact that fraud and deceit have no conscious or unconscious motive in this case; there was no purpose of gaining a certain end. Besides, the change of personality described above is a sufficient guarantee against the assumption of an intentional or conscious focusing of a malingering attempt upon one feature of speech—mutism.

The peculiarities of behavior, of conduct, of relationship to his parents and brothers and sisters, of judgment concerning his faculty of speech—all of which developed simultaneously and parallel with the mutism—designate a disability indicative of a profound mental disorder notwithstanding the fact that the boy was able to understand printed matter, that he was able to become interested in certain subjects, that he was able to answer questions in writing. The character of his acts and the total inability to criticise his own abnormal acts, his failure to observe the striking contrast between his present mode of acting or feeling and that of the former normal condition, the impossibility of appreciating the radical changes which have taken place in every detail of his life, are all evident proofs of the boy's perverted adjustment as a result of a change in his personality.

1812 SPRUCE STREET.

THE NATURE AND CAUSE OF STAMMERING.

BY MEYER SOLOMON, M. D.,
Chicago.

The terms stammering and stuttering are used synonymously in this paper. The speech apparatus proper consists of two portions: 1, the articulative organs, used in articulation or the pronunciation of consonants (the lips for labial, the point of the tongue for dental, and the back of the tongue for guttural sounds); and, 2, the vocalizing organs, consisting of the laryngeal apparatus, used in phonation, vocalization, or more plainly in pronunciation of vowels. Furthermore, changes in respiration are constant accompaniments of the act of speaking. Both articulation and phonation are under voluntary (motor) control, as is also, to a certain degree, the respiratory apparatus (chest movements).

Briefly summarized, the nature and cause of stammering can be presented as follows: The stammerer suffers from nervous excitability and emotionality; this expresses itself, in the stammerer,

in a speech disorder; the speech disorder in the stammerer is produced as the result of a definite series of phenomena, all of which are under the stammerer's control. First, there is the tendency on the stammerer's part to hurry, virtually to rush headlong and precipitately into speech expression of his thought. So great, so intense, so acute is this haste, that the stammerer really thinks faster than he can speak, and he endeavors to say immediately that which he has in mind. As a result of this, he throws his speech apparatus—either the articulative (for consonants) or vocal (for vowels) portion—into sudden, more or less, violent spasm. Respiratory spasm is commonly present in either case. In his blind rush the stammerer tries to pronounce a vowel (laryngeal sound) with his articulative organs—that is, while his speech apparatus is in the position for articulative (consonant) expression; or, he makes efforts to produce articulative sounds with his vocal (laryngeal) organs—that is, while his phonation apparatus is in action.

As a consequence the stammerer either maintains a fixed articulative (consonant producing) position and endeavors, while in this position, to pronounce a vowel; or, he keeps his vocal (laryngeal) apparatus in continued action while battling to proceed hurriedly and stubbornly to the pronunciation of a consonant. Both of these feats are impossibilities for any human being. One must cease articulative (consonant producing) efforts to pronounce a vowel, just as one must stop vocal (vowel producing or laryngeal) efforts to pronounce a consonant. The stammerer unthinkingly persists in his misdirected efforts to do the impossible—that is, to pronounce a vowel with his articulative organs (lips, tongue) or a consonant with his vocal organs (larynx).

In his insistence in this direction the stammerer may bring into play much of his voluntary motor system and assume, during the act of speaking, various accessory or supporting attitudes and postures, spasmodic in nature, just as one would in hard work or fighting or running. The stammerer may become exhausted from his efforts. Finally, in despair or by compulsion, the stammerer gives up the useless struggle, relaxes the portion (articulative or vocal, as the case happens to be) of his speech apparatus which up to that moment has been in spasm, and only then, often to his great surprise, is he able to proceed to the pronunciation of the next sound.

The stammerer wishes to say the word but. He begins, as he should, with the labial *b*, shaping the articulative organs to this end. Now, to pronounce the second sound, *u*, which is a vowel, the vocal (laryngeal) apparatus must be brought into play. The stammerer, however, is in so much of a hurry to pronounce the vowel *u*, that, not knowing just what he is doing, he does not take the time to relax his articulative organs (in this case the lips) before proceeding to the pronunciation of the succeeding vowel. Instead of this, the stammerer insists in pronouncing the vowel *u* with his mouth fixed in the position for the pronunciation of the labial *b*. He repeats the effort over and over again. The stammerer, in this case, is thus unable to proceed to the pronunciation of the vowel *u* until, for one

reason or another, he ceases efforts at articulation (in other words, opens his mouth) and permits vocalization (from the larynx). The inability of the stammerer to proceed from the vowel *o* (laryngeal apparatus) to the consonant *v* (articulative organs—tongue and lips) in attempts to say over, can be explained in an analogous manner.

The mental state of confusion and fear, with timidity, shame, embarrassment, feeling of inferiority, and the rest are but aftereffects. However, fear of stuttering in a stutterer leads to increased nervous excitability and hence to increased efforts to do the impossible, as explained above. Anything—fear, shame, embarrassment, malnutrition, overwork, or insufficient sleep—which enhances the stutterer's nervous excitability makes his stuttering or tendency to it worse. The therapeutic indications are simple, are clearly indicated, and will be discussed in a separate communication.

5501 PRAIRIE AVENUE.

NATIONAL MORALE IN RELATION TO HYSTERIA, MILITARY AND INDUSTRIAL.*

By TOM A. WILLIAMS, M. D.,
Washington, D. C.

The high morale which was preserved in the French Army, in spite of the discouragement of the rest of the world, must be largely credited to the work of the French neurologists. It prevented the defection of men on account of psychological inadequacies; other men learning thus that the functional nervous disorders would not get them out of the army, stiffened themselves against this temptation. In the British Army the problem had become unmanageable; 100,000 men were let go on account of functional nervous disorders, uncured because of the antiquated concepts by neurologists in that country. Later the British rather crudely imitated the French methods.

An uncured neurotic is a trouble maker, while a man who is cured is not only grateful but becomes an educational force against similar troubles in others. Much of the dissatisfaction among the laboring people in England can be attributed to the unskillful management of the neurologists, permitting these thousands of men to leave the Army and pervade those around them with discontent.

Insurance against what had happened in England was early instituted in the American expeditionary force, and a competent and adequate staff was provided to deal with functional nervous diseases. They had begun to do valuable work when hostilities ceased but the real demonstration of the value of good neurologists to a nation was given only by the French.

The great frequency of hysteria among soldiers has been thoroughly established during the recent war. About ten per cent. of the casualties bear the stamp of functional nervous disorders and the vast majority of these were hysterical cases. This is true not only of battle periods, but also during times of relative quiet, although the rate rises in

*Read before the American Medico-Psychological Association.

anticipation of important attacks. The depletion of the ranks is serious enough in itself, but when it leads to extensive discharge of trained soldiers from the army it becomes a great danger to man power.

The loss of man power is, however, the least important disadvantage of hysteria improperly dealt with. The effect upon other workers of thousands of incapacitated men without lesions is most pernicious, for the contagiousness of their example is pervasive beyond expression. This, too, was discovered by the British, but only after it had given rise to serious disaffection among the workers. The sight of what they called shell shocked men, providing apparently horrible examples of what might happen to themselves were they drafted to France, was not calculated to encourage the spirit of belligerency. Furthermore, 100,000 chronic invalids were a drag upon the national resources. When this was found, herculean efforts were made to recuperate these men at enormous expense, but with only limited success in spite of the exercise of very high skill. Had a modicum of this skill been permitted in the Army itself, no such problem would have occurred among the British.

The French entirely obviated these disadvantages by applying the neurological skill where its efficiency was at a maximum, namely, in the fighting zone itself, so that soldiers with functional nervous disorders were immediately differentiated, and treated where possible. Even where this could not be done, no discharge was obtainable, but the soldiers were sent to neurological hospitals in the interior until such time as organizations for their intensive treatment came into operation. In this way the French nation was spared the lamentable spectacle of complaining men with grievances against the Army and the country which had discharged them uncured and only too ready to disseminate alarm by emphasizing the awful horror of war to timorous lay people already exhausted by the privations through which they had to go to maintain the Army.

MANAGEMENT OF WAR HYSTERIA.

The treatment of hysterical manifestations depends upon one principle, namely, the replacement of the patient's morbid mental attitude by a normal one. It is a reconditioning, a substitution, a re-education to which the patient has to be persuaded.

The means of persuasion are innumerable. The most successful in the hands of one therapist are not necessarily those which should be employed by another. The choice depends far less upon the nature of the hysterical symptom, or even upon the nature of the patient's makeup, than upon the temperament of the therapist himself. Some men are most successful when they employ methods which in reality are pure suggestion; others are more successful if they use methods which make the patients suffer. Others again cure more cases when they are permitted to elaborate a systematized re-education of the patient.

Suggestion.—The methods which are scarcely more than direct affirmation and suggestion, are only of utility during the whirl of the dressing station at the front, at a time when the man's belief that he is justified in reporting sick is not at all

firm. The diagnosis can be made swiftly and easily. To restore the patient's military capacity it suffices to assure him confidently that his trouble has disappeared and that there is no reason for its return.

Torpillage.—The removal of hysterical symptoms by the infliction of suffering is applicable to perseverators and simulators rather than to the general hysterical patients. It is a method most readily employed by those physicians who have not the patience and the spirit of organization required for more systematic treatment. It is, of course, a very rapid method, saving a great deal of time for the doctor, and providing a great economy of man power, in that a patient treated in this way can be restored to the service in less than a month, whereas a patient in whom the more moderate method of influence and reeducation are employed required several months to become fit for service.

The severe and painful methods of treatment, however, are greatly restricted in utility unless they are completed throughout the army, unless the assurance that they will be employed is known to the soldiers, and unless their use is sustained by public opinion. When the chance of evading this treatment exists either because the patients knew that the doctor dare not push it or on account of fear of interference by political appeal, the treatment loses its authority and becomes a very painful ordeal for the doctor who uses it. Besides not every man has the tenacity, the courage and the skill required for its utilization. Mere relentlessness does not suffice. The doctor must know when to cease the painful stimulation and invoke the patient's own will in the removal of his disability, for intemperate zeal and bungling brutality inevitably produce a spirit of vindictiveness in those subjected to the treatment which has a detrimental effect upon the neurological services in general.

Reeducation.—Torpillage should never be attempted except in thoroughly successful hands. Accordingly, it is necessary to have recourse to the method of gradual reeducation. The principle utilized to effect the metamorphosis of the patient's mental attitude by this procedure is that of the building up of hopeful expectancy by the giving of examples of cure, and by other means calculated to create an atmosphere of confidence. The subject is more fully gone into in my forthcoming book on the disorders of the nervous system in warfare and also in a recent article (1).

PROPHYLAXIS OF WAR HYSTERIA

The best preventive of hysteria is that the soldiers realize that most of the functional nervous disorders are quickly cured, and give rise to no future diminution of military value; that shell shock rarely occurs even in men stunned by explosions; and that every man will immediately meet with skilful diagnosis and sympathetic treatment if he has to be taken from the line, but that any attempt to evade duty by the assumption or exaggeration of symptoms will be quickly detected and firmly dealt with.

I consider that the excellent morale of the French Army, under the most appalling conditions, was made possible only by the skill, fidelity and determination of the French neurologists, who persist-

ently kept before the soldiers the fact that functional nervous disorders should all be recovered from, and that no one could be absolved from army service because of them. However, so incomplete was the understanding of the nature of hysteria by the laity, even in France, that repeated attempts were made to interfere with the labors of the neurologists charged with the restoration of obstinate hysterics to active service. Emphasis was laid upon the severity of the treatment, by agitators, who would not or could not see that a temporary suffering necessary for permanent welfare was not only legitimate but essential. Those who never thought of objecting to the suffering contingent upon a surgical procedure, held up their hands in horror at the much less painful procedure necessary to overcome hysterics with contractures, persistent paralysis, deafmutism, stammering, tremor, convulsion, incontinence of urine, pseudogastropathy, or what not.

Subsequent to a court martial implicating Dr. Clovis Vincent, the newspapers so violently attacked his work at Tours that the intensive treatment had to be given up. This in spite of the fact that nine hundred men who had previously encumbered hospitals for months were returned by Vincent to the army in less than a year.

The newspaper *La Victoire* then attacked the establishment at Maison Blanche and destroyed its usefulness, in spite of the complete exoneration and high praise expressed by Gustave Herve, the editor, subsequent to a visit incognito to the hospital. He then wrote as follows:

"Our readers have certainly not forgotten unfavorable criticism of our neurologists. Because of what I had heard from different sources, I went to the Under Secretary of State of the Service de Santé and asked him to put an end to the cruelties that certain doctors were guilty of toward our wounded soldiers. In reply Mr. Justin Godart said: 'Let us arrange a day and without announcing our arrival we will go to the Maison Blanche where these horrors you have told me of take place.' We paid our visit together, and I will give a short account of what we saw.

"About sixteen kilometres from Paris is situated a hospital which before the war was used for the treatment of the insane of the Department of the Seine. It is called the Maison Blanche.

"The hospital was disinfected. It is a beautiful place with large courtyards and garden, large windows giving plenty of light and sunshine can penetrate. It is here that the wounded are cared for while waiting for their artificial limbs with which everyone is provided. In three separate pavilions the soldiers suffering from nervous diseases are treated by nerve specialists.

THE WOUNDED.

"We were taken first of all into a large room where under the direction of Professeur Amar the artificial limbs are suited and reeducation exercises are given according to the methods of Dr. Amar, which greatly diminish the incapacity of the wounded. The artificial limbs are as perfect as possible; the doctor himself fits them with the greatest care. After many experiments the manufacture

of artificial limbs has been standardized and soon the wounded will not have to wait for them as they have done in the past.

THE NERVOUS CASES

"The effects of the war upon the nerves are sometimes very unexpected. Sometimes they are the direct results of the wounds, and sometimes there appears to be no direct reason for them.

"The patients are cared for in two large pavilions furnished with beautiful white beds, and with large windows. Some have lost the use of their legs, and others walk bent double; this one was deaf, dumb and blind, but already he sees, hears and is beginning to speak. A Zouave trembles so that he cannot stand up. The toes of a soldier were entirely turned back (*retournés*). This would all be very terrifying if the doctors did not assure me that all these unfortunates are curable, and if I had not seen those who were nearly cured.

"The mechanical treatment is unfortunately rather rough; it is necessary to reeducate the limbs which do not obey the will and the necessary muscular tractions and those that do not understand. They are in fact very painful for the patient who does not always understand how necessary they are.

"I questioned all the patients one after the other quite openly; some know, some do not understand, and it is certain that when these patients told their families of the treatment they had received and which they were made to undergo, these misinformed relatives became agitated and judged with severity the tortures the soldiers had undergone.

"In order to prevent the natural but very unfortunate judgment which the best intentioned patients can give about the procedures which they cannot explain, it is necessary to limit the visits of the relatives. It is necessary for them to know that if their children suffer, this suffering is necessary and that the results legitimate it.

"The patients I have met have talked with great freedom, with one or two exceptions, accept willingly the care given them.

"I have even seen the cells in which the patients are placed who are in need of complete isolation. They do not at all resemble the cells of civil or military prisons. There is absolute solitude and it is not at all gay but it is clean and light, the doors have glass in them, there is good fresh air and a comfortable bed. No essential is missing and I am only too happy to say that my apprehensions were unjustified.

"As for the patients they should wish to be cured as much as we wish it for them and so the only possible means of cure must be accepted. The parents should have no fear, they should understand that one wishes to return to them and to the nation their children sane and healthy and that there is nothing to do but to leave the matter in the hands of the doctors specially trained for the diseases. Every one must be patient and have confidence and it is not at all necessary to say to these doctors who undertake the treatment of the nervous patients that gentleness would accomplish more than violence; it seems to me that they do their work with science and kindness.

"The above is the account of what I saw. I hope that the relatives of these patients who know our desire to discover the truth will now be consoled and reassured."

On account of the likelihood of misunderstanding by families and friends causing friction and perhaps public agitation which would interfere with the task of physicians and the efficiency of the service, patients needing treatment by isolation and reeducation should be sent to regions inaccessible to families or other sympathizers.

In addition it is important that such a centre should be away from drinking shops, cafés, or any amusement, and that it should be protected from all kinds of smuggling. The less distraction the patients can find outside, the greater the impression made upon them by the atmosphere of the service itself, and the desire to enjoy again the pleasures of which they have been deprived is an additional stimulus to their own efforts to recover. There is every reason to found such establishments near the front lines, and on no account should patients of this description be returned to the United States. On the contrary, there should be a widespread understanding that such patients will remain in the military hospitals near the front.

On the other hand, the impression must not be allowed to originate that these hospitals are centres of coercion. For, although strong persuasion is needed to arouse the patients' efforts at cooperation, and severe discipline is often imposed, yet the object is primarily therapeutic, and for the patients' own good, as well as having the object of restoring a soldier already trained to his duty, and of preventing the demoralization which would occur if psychoneuroses were found to be an easy way for the perverse willed or cowardly to evade service or responsibility. A mutiny might be organized by a spiteful patient with ability. To prevent this, such hospitals should be under military law. When sent back to the regimental depot, patients who have been cured of hysterical attacks or the simulation of them are likely to manufacture a relapse, hoping that it will catch unawares the medical personnel without neurological knowledge.

The nature of industrial hysteria and its management has been considered by us in many publications, generally under the rubric traumatic neurosis. Latterly the method I have advocated of using the neurologist as a referee has been employed in Washington, much to the facilitation of adjustments and the avoidance of litigation.

Even as late as 1918 further attacks were launched against the very gentle methods employed in the centre of the seventh region, to which then nearly all the recalcitrant neurotics were being sent to undergo a cure by the progressive persuasion which was the method adopted by Roussy and Boisseau there.

SOLDIERS AND CIVILIANS

Campaigns of this kind are to be feared in any country. They have occurred in the past against surgical hospitals; even now they continue against many kinds of scientific research, especially that occupying itself with experiments upon animals.

No more need be said about this sociological question, as its merits are fully set forth in various pamphlets issued both in England and America by research defense societies and medical organizations.

The agitation against the French neurological centres has perhaps been in part aroused by the zeal with which some French neurologists have pursued their ideal of duty to the country and the cause of the Allies, for some of these men have thought less of their personal relation to possible blame than they have thought of the welfare of the patients, and hence they have failed to safeguard themselves against unjust aspersions. The best weapon against unjust agitation, is, of course, instructed public opinion. It is this which has sustained the practice of surgery in hospitals so that it is no longer a question of debate, and it is this which has sustained in the main the physiological experiments on animals.

In the United States, public opinion is already in a better position to comprehend the complex and difficult problem of the care of the psychoneuroses than it is in England, for instance. For in America the public mind has been saturated for twenty years by the facts of the influence of mental states upon bodily conditions, and by the knowledge that there are such things as psychogenetic disorders. This is already a step in advance, even though it has been taken in the main at the instigation of protagonists who inculcate also erroneous doctrines, and carry the psychogenetic factor to absurd lengths. This, however, is because of their ignorance of the facts of psychology and medicine when it is not from motives which are far from disinterested. We are referring, here, of course, to the teachings of the numerous mental healing cults, whose influence has been far more pervasive than most doctors realize. In order to amplify the information spread by them, it is only necessary to rectify that portion of it which is erroneous, by giving to the public clear and well illustrated examples of the limits of psychogenetic possibilities. This, of course, cannot be done in a day, but from each judicious presentation there should emanate a few individuals who will form an enlightening focus which would gradually spread its influence in the community where they live.

The present reporter has, for the past ten years been endeavoring persistently to spread, not only in the medical profession but among the laity and especially the women, the principles and the limitations of psychotherapy, and in some of the communities in which this has been done, the results are already apparent. One of the practical corollaries of this teaching has been the necessity of treating psychoneurotics, not by means of laymen or even psychologists, but by physicians only, for it is only they who are sufficiently trained to appreciate the physical factors which are constantly changing in every case, and without an appreciation of which psychotherapy often proves hurtful rather than beneficial.

The mental hygiene movement, too, has done something in this direction, but as it has been occupied

in the main by the grosser practical problem of the prevention of the physical states which produce alienation, it has not yet attained the influence which it will have with reference to psychogenetic disturbances. However, through mental hygiene organizations it will be possible rapidly to reach the public now, and to instruct them in advance concerning the rôle of the military doctor in dealing with the numerous psychic affections engendered by the continuance of the war. It will be much better to do this in an organized, sane and temperate fashion through a well balanced committee of mental hygienists than to allow it to be done by medical journalists who are prone to forget their educative function in pandering to sensationalism and mysterymongering in order to obtain higher prices and a wider circulation for their effusions. The facts, on the contrary, should be presented in the most simple, clear and demonstrative fashion; and the theme, which is full enough of sensationalism, should be shorn as much as possible of that element. The mode of presentation adopted by Dr. Addington Bruce, of Cambridge, and Dr. Evans, of Chicago, in these explanations cannot be taken exception to, as both of these writers present their subject as truthfully and sanely as is in their power.

I am aware that it is a dangerous field to permit public discussion to enter into, and that the task is difficult; but in view of what has happened in England, and to a far lesser degree in France, it seems imperative that we should not adopt a *laissez-faire* attitude towards the possibility of a situation which foresight may be able to prevent, and which threatens to such a degree that we can be certain of its occurrence unless something happens to prevent it. We cannot afford to leave to chance the occurrence of more favorable circumstances. By intelligent prevision, we may be able to prevent what we fear. A good deal will depend upon the ability with which the preventive measures are undertaken.

The public already recognize the need of a certain amount of suffering in the cure of disease by surgery, and especially in orthopedic work. The difficulty of explaining to them that the cure of psychoneuroses cannot be accomplished upon a bed of roses should not be insuperable. Furthermore, as the public has already accepted the principle of compulsory vaccination which entails temporary suffering for the prevention of disease, there is no logical bar to its accepting the principle of some degree of temporary discomfort or unpleasantness for the prevention of nervous disease. Further, as the public has long ago accepted the principle of compulsory education, which is, for the child, an exceedingly unpleasant experience as compared with the free life it might otherwise lead among the alleys of the city of the hedgerows and streams of the country, there should be no logical bar to a general acceptance of the principle of compulsory reeducation for the men who have fallen into a condition which imperatively requires it.

To the objection that medical science is not perfect, and that medical men are very far from it, and that some doctors are negligent, some incom-

petent and some harsh, we can reply that no one proposes to abolish the school system because some teachers are incompetent, negligent or harsh, and nobody advocates the abolition of surgery because some surgeons blunder and others operate merely for profit. In every art we have to set against the human imperfections the many excellencies and accomplishments; and so in the art of reeducational psychotherapy.

The war has furnished us with statistics which show that in the best hands with early treatment under good conditions, the recovery rate approaches one hundred per cent., and that even old, obstinate and resistant cases are cured in a proportion from eighty-five per cent. to ninety-four per cent. when the conditions for doing so are properly organized. Even men not of the highest skill, practising under conditions far from ideal, are able to restore to health about seventy per cent. of the psychoneurotic soldiers who pass through their hands. It is quite true that there are certain areas which are regarded as dumping grounds where the patient has little hope of improvement; but that simply affords an illustration of the wrong man for the job, and it is a situation which should be easily avoided in the American service, which has at its disposal a very large number of men, so that a man who does not succeed with the psychoneuroses can very easily be transferred to other work.

Some of the facts regarding the question in which it might be desirable to instruct the public are as follows:

As the motive of many men with psychoneuroses is, at root, a desire to avoid their duty, some of them will resort to any expedient to prevent themselves from being cured, provided that the said expedient does not give them the air of dodging an obligation. In France some of the men, after realizing that the treatment will be painless and that once in the hospital for treatment they have every chance of being cured in spite of themselves, have adopted the dodge of refusing to enter the hospital, basing this refusal upon the principle of the liberty of the individual to choose what treatment he shall give to his own body. This implies a refusal to submit to a medical or surgical prescription. This is regarded as a civil right, and even in the military service, the right has not been abrogated. This civil right is, however, abrogated in cases where the question of mental soundness enters, provided that there is danger to the patient himself or others. In the case of a psychoneurotic there is nowadays no dispute that the mental factor is the primary and all important one; so that fundamentally we are dealing with what in reality is an instance of mental unsoundness—if we are entitled to give that term to social inadaptability.

Where the defense of the country is concerned such behaviour as a fatuous refusal to take steps which will end in making oneself fit for service can be stigmatized justly as a danger to the nation. Furthermore, there is no doubt that the life of these men uncured is, if not a danger, at least a serious detriment to themselves and their relatives. They become a veritable nuisance to their community, absorbing an untold amount of wasted

sympathy, besides using up material resources which might be better applied in the upbuilding of the country. Such men, too, live under a sense of grievance against a community which has permitted them to lapse into a state of desuetude, and, worst of all, they form a bad example as to the possibility of such serious consequences happening to any one. Thereby they propagate a false impression as to the sequences of warfare which are bad enough without adding unnecessary contingencies.

These very men, on the contrary, after they have been cured are full of gratitude and recognition for the transformation which they have undergone. The letters written to the doctor who has cured them are only a few of scores expressing the intense personal satisfaction derived from their restoration to active participation in the affairs of life. No longer a cowering neurotic, the patient becomes happy to take his place beside his comrades, even in the danger zone, proud of the consciousness that he is a man once more and able to take part in the defence of his country. He learns how false has been his view of the beneficent physician who has cured him in spite of himself. He has found that the school which he dreaded was nothing like so hard as he had anticipated, and he is grateful for the privilege of having been chosen to pursue the salutary discipline which has retrained him once more into a man.

All these benefits will be abrogated if, by the fatuous pushing to an extreme the principle of individual liberty, there is dangled before the eyes of recalcitrants, sophists or weaklings, the opportunity of easily evading the duty of taking advantage of the means to make oneself fit. And yet, the argument is so specious that it has led away a great many into this dangerous counsel. They neglect the fact that we are at war, and while they do not grumble at the far greater hardships involved in the restriction of food and in the liberty of travel, in the shortage of wheat and transportation, yet they swallow this camel and strain at the gnat of personal privilege where the restoration of health to the sick is concerned. Let such objectors look for a moment at the disastrous example furnished by the ineptitude with which psychoneurotic patients have been managed in the British service, where over one hundred thousand men have been discharged unfit from this cause. Let them reflect upon the loss of fighting efficiency of this number. Let them reflect upon the pernicious example furnished by these cases to the rest of the Army, and the softhearted persons who attend to them at home. Let them think of the wastage of personnel and materials used up in their cure, and the enormous expense to which the country is now being put in belated efforts to do now with great difficulty what could have been done with comparative ease in the early stages of these men's trouble, namely, to reeducate them into useful citizens. A further expense to the nation is the enormous pensions which these men are receiving, and which the country can ill afford to pay. This would have been entirely unnecessary had the correct treatment been given them in the first place. It is this eventuality with which we are faced if the stalkinghorse of personal

liberty is permitted to be used to interfere with the essentials which neurologists know are required for the restoration to health of patients of this kind.

The fundamental need in organizing the treatment is the fabrication of a moral atmosphere of the most delicate construction; and ill advised interference on the part of those ignorant of the complexity of the problem inevitably destroys the atmosphere which is the chief requisite for success in the treatment of these unfortunate patients.

Before rushing into public discussion, either in Parliament, in public meetings or in the press, it would be a wise move for those who honestly believe that they have a grievance to bring it before some of the neurologists who have dealt with these patients. The information gained in this way would rectify the misapprehension of many. There will be some, however, who from lack of imagination are incapable of the insight required to understand the question. These people, however, being less clever, are less dangerous. The most dangerous of all are those who are disingenuous, and, at the same time, clever. Their testimony is, however, often discredited in advance when their character is known.

RHYTHMIC ELECTRIC CURRENTS IN THE TREATMENT OF ABDOMINAL AND PELVIC RELAXATION.

By G. BETTON MASSEY, M. D.,
Philadelphia.

I have sent many messages to those of the medical profession interested in the possibilities of electric power in gynecology, but none of more universal application and usefulness than the few words I shall now have to say of rhythmic currents.

A well known colleague, who had never placed reliance even in the past on a single remedy, though it be the knife, accosted me recently with the question: "I have a lot of women coming here in the afternoon office hours. What kind of electricity can I use for them?" Having a vivid recollection of another surgical gynecologist asking me if putty wouldn't do as well as potter's clay for a dispersing electrode on the abdomen I was puzzled for a moment. The answer then came at once: rhythmic currents. The chances were that nine out of ten of the patients would be benefited by this modality, even administered by the nurse, and that the tenth might possibly be made more comfortable, and surely no worse.

A rhythmic current differs from the older methods of electric neuromuscular stimulation in that waves of stimulation are produced by mechanical means that have a rhythm adapted to the normal muscular impulses of the part treated. Their administration may be continued for a half hour at a time without fatigue (either to the patient or the operator), and present the best solution of the problem of how best to restore muscular tone to

the muscular organs of the pelvis and abdomen. Being rhythmic, and therefore painless, we can use enough current amperage in waves slow enough to stimulate the smooth muscular fibres of the uterus, tubes, and intestinal muscular coats, while at the same time contracting the striated muscles of the pelvis and abdominal wall.

These currents, produced by more or less perfect machines, have been called sinusoidal from the shape of the basal wave of the current, but only what was known as the slow sinusoidal was rhythmic with normal muscle contractions. The curve of the galvanic sinusoidal current is rhythmic, when the waves are slow enough, but unless what has been called the rapid sinusoidal current surges in *cre-scendo* and *diminuendo* waves not faster than fifty a minute, with selection of slower surges down to about twelve a minute, it is not rhythmic. These rapid waves are themselves from forty to seventy-two thousand a minute.

Our handicap in the past, and even now when rhythmic surges are not used, was that a current had to be turned on smoothly, turned off, reversed, and turned on and off again smoothly by hand repeatedly, for half an hour, to be of equal value. This was tiresome, even when a nongalvanic current did not need to be reversed but only surged. The result was that a continuous, unwavering stimulus was applied to a part that normally contracted and relaxed in slow waves.

I leave the practical indications of this remedy to the good sense of both trained and untrained gynecologists. It is self-evident that a wave of power that can reach and contract intestinal muscles, for instance, in a manner tending to restore their normal tone, is better than merely taking tucks in these tubes or structures; and that when a torn muscle has been repaired, as in the perineum, further effort to restore the power of the muscle should be made.

1823 WALLACE STREET.

FIRST AID IN INFANT FEEDING.

BY JACOB SOBEL, M. D.,
New York,

Assistant Director Bureau of Child Hygiene, Department of Health;
Professor of Hygiene, Fordham University School of Medicine.

Infant feeding may be a complex problem, a song of many stanzas, as it has been called, but the refrain—yesterday, today and tomorrow—must always be breast feeding, if we hope to conserve the health, growth, development and life of infants to the greatest degree. In fact, we may say that there are three first aids in infant feeding—1, breast milk, 2, breast milk, and 3, more breast milk, and of the three, the last is by far the most important.

I have no quarrel with the cow. In her place she fulfills an important part in our socioeconomic sphere. However, I do not know but that I may appear somewhat unorthodox in an exposition of this kind, in which the slogan is "milk is Nature's most valuable food," if I preach the gospel of "mother's milk is the infant's most valuable food."

But I would not be true to myself and to the large number of infants whom it has been my privilege to supervise, in private practice and in public health work, for over twenty years, if I did not tell you frankly that I will boost the mother and not the cow. If then, during the course of my remarks, I should emphasize mother's milk for mother's baby rather than cow's milk for mother's baby, you will realize, I hope, that while this attitude may be bad for the milk business, it is best for the infant.

Let me say at the outset that I am entirely in accord with the statement of Dr. McMurchy that a mother should not sublet her duty to a cow. The problem of infant feeding is not merely a temporary one, a problem of preventing the immediate ills of gastrointestinal disturbances, malnutrition or marasmus. It aims further, in that it endeavors to secure the maximum growth, development and resisting power of the infant, with a minimum by-derangement. Feeding in early life determines in a great measure whether the child or man of the future will be a weakling, or strong, robust and vigorous, physically and mentally. With Riha, "I hold a dietetic creed that no amount of proselyting can take away from me, namely, that the majority of gastritides among adults have their origin in the gastroenteric insults of infancy and early childhood."

It is entirely unnecessary to present in detail the reasons for the superiority of breast milk over cow's milk in infant feeding—however pure, safe, clean and properly cared for and prepared the latter may be. It is sufficient to remind you of the lower morbidity and lower mortality among breast fed infants, especially from diseases of the gastrointestinal tract; of the greater and more rapid growth, development, resistance and recuperative powers of breast fed babies, and perhaps, their greater mental development; of the presence in the breast milk, and particularly in the colostrum, of immunizing and protective substances; of the greater assimilability, adjustment and adaptability of breast milk in and to the infant's stomach and digestive powers, and its greater ability to strengthen the stomach; the automatic adaptation of mother's milk and the secretion of the infant's gastrointestinal tract; of the ideal composition of human milk, in that it contains the necessary health and growth giving food constituents in proper proportions and in comparatively uniform amounts; of its proper temperature at all times; of its freedom from harmful bacteria; and its ever readiness under proper healthful and physiological conditions and environment of the mother. Moreover, it is a common observation that even under unfavorable hygienic surroundings, the mortality among breast fed infants in the tenements is comparatively low.

There is, in other words, something about breast milk which enables the baby to put up a better fight against the many dangers with which it is surrounded daily. Truly, breast milk is the infant's elixir of life, and an ounce in the breast is worth two in the bottle. Surely, a food of this kind is one devoutly to be wished for by every infant. Indeed, if the infant could talk, or if, to apply an expression used by one of our famous car-

*Presented at the first session of the New York Child Health Conference, held at the Academy of Medicine, May 19, 1920.

toonists, we were to ask ourselves, "I wonder what a baby is thinking about," we would find it saying or thinking, "I wish my mother would feed me on what Nature intended I should have." But infants cannot talk and therefore it remains for others to file a brief in their behalf and to leave no stone unturned in teaching and urging every mother to breast feed her baby.

An infant that is deprived of mother's milk is essentially and physiologically a premature child. It is said that the baby kangaroo attaches itself to the mother's nipples, clings fast, and only lets go when it is fully matured. Chapin says, "Nowhere in Nature do we see that parents leave their young until the young are able to secure food for themselves; if the necessary food is not all derived from the parent's body, suitable food is provided until the young is able to look out for itself." Most of the newborn of the lower animals are able to look after themselves within a comparatively short time and guard themselves against attack and injury of all kinds. Unlike the lower animals, it was never intended that an infant should shift for itself, but rather, that it should depend for its food, its shelter, its clothing, its comfort and care, for its very existence, upon the aid of its parents, especially the mother, and, in proportion as this aid is good, bad or indifferent, will the future man or woman become a credit or liability to society.

Breast milk is in a sense quite as essential for the nourishment of the child after birth, as the placental circulation is during the prenatal period, and it would be better if we were to consider that an infant should be nourished by the mother approximately eighteen months, nine months through the placental circulation, and nine months by the breast.

Granted, then, that breast feeding is Nature's way, it is plain that we should strive to have one hundred per cent. nursing, if it is possible. In fact, the vast majority of mothers can nurse their babies if they will it or desire it. There are legitimate exceptions, it is true, but they are few and far between. Unfortunately there is a feeling abroad in certain quarters that the capacity for lactation among mothers is less these days than in former years. This is not true in my opinion. The capacity is as great today as ever it was; and if there is a tendency in some places toward diminished maternal nursing, it is due rather to unfortunate economic conditions, which force mothers to engage in gainful occupation; to poor food and housing, which undermine their health; to unwillingness or indifference; in some quarters to pressure of social duties; to the entrance of women into political and social spheres; or, to the only too frequent custom among many physicians and institutions, to tie back the breasts, a few days or weeks after the birth of the child, because the flow of milk has not been as rapid or sufficient as was anticipated, or because of the discouragement of the mother as to the establishment of a promptly functioning breast. The latter in my opinion is a fatal mistake and frequently means the loss of the breast milk to the infant. Even in cases where there has been apparent loss of breast milk, placing the infant to the breast every three or

four hours, combined with diet, exercise, a ready assurance to the mother of success and a healthful frame of mind, it is possible to restore the secretion of an apparently nonfunctionating breast and have it continue for many months. It may be taken as axiomatic, that the further the mother is removed from the home the less the likelihood or possibility of successful breast feeding. Motherhood should not be sacrificed to society. There are few breasts that cannot be made to functionate properly, if the infant is applied frequently enough—not too frequently—every three or four hours, let us say, and if the mother has the necessary hygienic and dietetic care, proper, liberal, wholesome well balanced, palatable, enjoyable and sufficient diet, food to which she is accustomed, good teeth, skin and bowels properly cared for, rest, sleep, exercise, recreation, encouragement and particularly, mental poise.

Aside from those cases of congenital malformation of the breast and nipples or insufficient mammary development which make nursing imperfect or impossible, I might say that from the viewpoint of infant feeding, there are no malfunctionating breasts; they are all good, but some are better than others.

There are some lessons to be learned from the cow. She continues to calf year after year for several years, and to be milked day in and day out for the greater part of each year and continues to give milk of sufficient quantity and good quality, provided, of course, that her food and environment are sufficient and proper. Many mothers, on the other hand, and unfortunately many physicians, consider the mother's milk improper or insufficient after several months, or, indeed after several weeks of nursing. The cow seems to feel that she has been placed here for a purpose, to be milked, and she appears happy and contented with her task. She never seems to tire giving milk. She seems to see her duty and she does it. Can we say the same of all mothers? I recognize the shortcomings of this comparison, but the point which I wish to bring out is the fact that we seem to spend more money and care on the health and efficiency of the cow and her milk than on the care, health and life of the mother. Shall we confess that commercialism is considered of greater moment than humanitarianism? The truth of the matter is that a large part of what applies to the cow applies to the nursing woman. It has been found, time and again, that wet nurses in foundling and infant institutions can nurse one or more infants for a considerable length of time, for one or two years, and give them proper nutriment if their breasts are stimulated by periodical suckling, if they are well emptied, and, if their food and surroundings are in keeping with the maintenance of good health.

While it may not be possible or desirable that an individual mother should continue lactation longer than nine to ten months, or perhaps, during the first year of the child's life, it is a fact that the great majority of mothers can nurse their infants if they so desire, or, if the physician persists and insists in surrounding them with all the essential factors for establishing and maintaining a proper supply. In fact, such noted clinicians as Finkelstein,

Schlossman and Engel, have said "there is practically no limit to the period of lactation of a good wet nurse, and that the breast will continue to secrete a good quantity of milk so long as the stimulus of suckling is supplied." That these are true statements I have reason to believe from the many years of observation and from my own personal experiences in which I was able to reestablish a satisfactory supply of milk in the breasts of women who for one reason or another had discontinued such feeding at the time the infants came under my personal care. Most breasts can be educated into giving a liberal supply of good milk, by persistence on the part of the physician and the mother.

If but a small fraction of the time, energy, and thought that have been given by physicians to the elaboration of the different methods of artificial feeding, to say nothing of the vast amount of money spent by commercial concerns in propaganda directed to convincing physicians and the public at large that their proprietary *foods* are God given substitutes for milk, were devoted to the study and encouragement of breast feeding, the bottle fed baby would be the great exception. There is no perfect substitute for mother's milk. Science at best can only approximate it.

Truby King says, "The mere changing of the percentage of the food elements in cow's milk, to correspond with those in breast milk, does not by any means change cow's milk into mother's milk. The differences are far more subtle than mere percentages." No mother should be permitted to feed her baby artificially unless some direct and definite contraindication to breast feeding exists—tuberculosis, epilepsy, insanity, chronic wasting disease, extensive infection of the breasts—or, until the physician is convinced beyond any doubt that all known accessory measures have failed to arouse the breast to activity. Even if there is only sufficient breast milk at hand for one or more feedings these should be given and supplemented by cow's milk for "every drop of mother's milk is precious to the baby, especially during the first months of life."

The activity of the breasts depends largely upon the stimulation which they receive, and the best stimulus is the suckling of a vigorous infant. Here too, we can learn much from the cow. The farmers soon found that unless the udder was emptied at each milking and unless the milkings took place at sufficiently frequent intervals, the cows did not give a full amount and in time ceased to give milk at all. The failure of milking machines was due to the fact that they did not empty the udders and the cows gave less milk than in hand milking. So it is in the human breasts. Unless the child is placed at the breast at frequent intervals and the breasts are emptied, they soon functionate imperfectly or cease to functionate altogether. For an efficient emptying of the breasts it is necessary that the infant be hungry and too frequent feeding, that is, every two or two and a half hours, makes the infant less hungry, less desirous of suckling and therefore less likely to empty the breasts. Besides, the end milk of the breasts, as well as of the udder, contains the bulk of fat and therefore if the breast is not emptied the child does not get sufficient nourish-

ment. Too frequent feeding and improper suckling, therefore, have a deleterious effect upon the nourishment of the infant as well as upon the milk supply of the breasts. While mechanical or artificial emptying of the breasts—sometimes necessary in the case of frail and delicate infants and in acute illness of the mother, by the use of breast pumps, affords a certain amount of stimulation, like the milking machine, it is at best, a poor substitute for the natural method of suckling by the infant.

One word of caution in regard to breast feeding. Despite its great value and its advantages over artificial feeding, there is sometimes a tendency on the part of mothers and physicians who desire to persevere in this method of feeding to continue its administration too long even though the infant is not thriving; that is to say, either remaining stationary in weight, losing in weight or otherwise suffering from indigestion. Breast feeding must be conducted in a practical and commonsense way. Therefore, it has been well said by Reuben, "good breast milk is better than good artificial feeding but good artificial feeding is better than poor breast milk." On the other hand there are mothers who are reluctant, because of fancied or imaginary reasons, to suckle their young and who have been led to believe by friends and neighbors and often by some physicians to regard feeding with cow's milk as just as good as breast milk. The best answer to give these mothers is to tell them the story quoted by Jacobi: Old Dr. Heim was told by a so-called noble mother: "I keep an ass for my baby. Ass's milk is as good for my baby as my own milk would be, is it not?" "Yes, yes," said the old man, "just as good for young asses."

Dr. Chapin has started the call "back to the home" for the supervision of children deprived of a mother's care. It is high time that we take up a similar call with reference to the feeding of infants and proclaim "back to the breast."

But, after all, I must confess that an unnecessarily large number of infants are deprived of what is theirs by right, mother's milk, never through any fault of their own, frequently through no fault of the mother but often because of the failure of municipalities to surround the expectant mother with those safeguards which make for the protection of her life and the maintenance of her health. Too frequently we forget that "the baby's life and pathology begin nine months before its birth." There is something so interesting, so human, so tangible, so dramatic about the newborn baby, that we fail to realize that the condition of the baby at birth and for the greater part of the first year, depends largely upon the care of the mother before its birth. The question of breast feeding therefore arises or should arise, long before the birth of the baby. Since it is admitted that breast feeding is the method of feeding par excellence, and since the ability to nourish the infant depends upon the health and vitality of the mother, it follows that all efforts should be directed toward preparing the breasts to functionate properly at the time of the birth of the baby. To me, therefore, the very first aid in infant feeding consists in a proper supervision of the expectant mother.

Aside from the many advantages which accrue to mothers and infants, as the result of proper prenatal care, let us concentrate upon the relation of this care to the infant's procurement of what is its birthright—mother's milk. It is safe to say that the better the prenatal care received by the mother, the greater the likelihood of her desire and ability to nurse the baby. It is a sad commentary upon the progressiveness of our country to find that the United States is fourteenth in the list of countries of the world as regards maternal mortality rates relative to pregnancy and seventh in the list as regards the infant mortality rate. In other words, in thirteen other countries the life of the mother during pregnancy is safer than in our own country.

I wonder whether many people stop to consider the relation between prenatal care and breast feeding? Whether they stop to consider that the first aid is placing the mother in such a condition during pregnancy that she will not only desire to nurse her baby but that she will be alive and healthy enough to do so. But even that is not enough. We must also surround her with all necessary precautions which will enable her to bring into the world a vigorous and healthy baby, one who will suckle well and by such stimulation maintain a proper and sufficient flow of breast milk. Why then, is prenatal care so important in relation to breast feeding? The answer is to be found in the maternal and infant mortality and morbidity statistics incident to pregnancy. Here is the indictment with its many counts—and to which future civilization must answer "guilty" or "not guilty."

1. The Federal Children's Bureau makes the statement that more women of the child bearing age, fifteen to forty-five years, die from conditions incident to pregnancy than from any other single cause except tuberculosis. Dr. Henry C. Davis says, that "the records of life insurance companies show that for all women who are insured under forty-five years of age the diseases of pregnancy and the puerperal state are the second greatest causes of death." The Metropolitan Life Insurance Company makes the statement, "that it is a national blemish that the death hazard involved in bearing children, is greater than that in mining coal or in railway services." Death robs the infant of mother's milk—of mother's care. While in recent years, the deaths from many communicable and other diseases have been reduced materially, the mortality incident to childbirth has shown comparatively little appreciable reduction.

2. A large number of maternal accidents and injuries incident to childbirth and of other conditions occurring during pregnancy undermine the health and vitality of mothers, result in infections of the breasts and nipples and other conditions which make the mother a chronic invalid and prevent her from nursing the baby, however anxious and willing she may be to do so. The saddest feature of all this is that very many of these conditions are preventable. As Dr. George Newman puts it, "A vast number of women are made invalids for life or lose a large part of their economic value or become sterile or die ultimately from injuries received or disease acquired while fulfilling or

attempting to fulfil the functions of motherhood."

3. Over forty per cent. of all deaths during the first year of life are due to congenital diseases which are dependent in a large measure upon improper care received by the mother during pregnancy; and here too, a large proportion of these deaths are preventable. In fact, during the years 1918 and 1919, the infant mortality statistics for the city of New York showed that more deaths were ascribed to congenital diseases alone than to diarrheal and respiratory diseases combined.

4. About forty-two per cent. of the deaths of infants under one year of age take place during the first month of life and the majority of these deaths are due to congenital diseases, prematurity, debility, marasmus, convulsions, accidents, injuries, etc.—conditions which often call for mother's milk as a life saving measure. With a mother dead or invalidated because of improper, insufficient, or no prenatal care, what chance has the majority of these infants?

5. While statistics show that the infant mortality rate as a whole and the rate from the second to the twelfth month of life have shown a steady decline in recent years the infant mortality rate under one month of age has remained practically stationary. Since the vast majority of deaths during the first month of life are due to congenital causes, largely dependent upon the health and environment of the mother during pregnancy, and to conditions in which breast milk would prove a life saving measure, the importance of prenatal supervision is selfevident.

Wherever and whenever intensive prenatal work has been conducted by municipalities, by private organizations or by large insurance companies, the maternal and infant mortality and morbidity among these selected groups of expectant mothers and their infants have been considerably lower than among similar unsupervised groups of the community. In witness whereof we point to the results of the Bureau of Child Hygiene of New York city, the maternity centre associations, the Metropolitan Life Insurance Company, and to similar results in Boston, Pittsburgh, Cleveland and other cities.

There are many other statistics recorded in previous publications which I could quote in justification of the urgent need of systematic prenatal care, but I have purposely limited myself to those which bear directly upon the question of breast feeding. In the face of such a presentation can there be any doubt of the verdict of the jury—the public—as to the immediate and direct need of placing at the disposal of every expectant mother all necessary information and material assistance for her own safety and that of the newborn infant. Society owes a debt to the expectant mother which it must discharge. It is not enough to await the arrival of the baby and then proceed to look after the breasts. The way must be paved by prenatal care. Instruction and supervision of expectant mothers will, as numerous studies and experiments have demonstrated, give in most cases a healthy mother and a healthy infant; and if as a result of the intricacies of Nature and despite all prenatal care, there

is born into the world a puny, delicate infant, the existence of a healthy mother with an abundance of good breast milk is the best health and life insurance policy that the baby could have. With all these facts before us, with a knowledge that breast feeding is God's way, that prenatal care is the most pressing, urgent and direct need of the present for the protection and conservation of mothers and babies, with the indifference shown on the part of most cities in the organization of a corps of prenatal nurses, it is not too much to predict, that soon the citizenry of our country will cry aloud, "How long, oh municipalities, will you abuse our patience?"

In spite of all the known and frequently repeated argumentative data in favor of prenatal care, a thoroughly organized municipal service for such care exists in comparatively few cities. It seems as if private and semiprivate philanthropic and social organizations have seen the light of this great need to a degree far in excess of that evinced by municipal authorities, by the organization of maternity centres which seek to coordinate in localized sections all existing facilities for the examination, home or institutional supervision, care and treatment of expectant mothers. Why this is so is difficult to understand, unless it is that the results and possibilities of prenatal care are not so immediately or directly demonstrable as those of infant mortality control and for this reason those in charge of city funds hesitate to make the necessary appropriation.

Prenatal care has a double purpose to perform—the giving of a healthy mother to the newborn infant, and the giving of a strong and vigorous infant to the mother. Without a healthy mother there is a possibility and likelihood of insufficient breast milk in quality and quantity; without a healthy infant there is a likelihood of inability to suckle well and the danger of improperly functioning breasts. The interdependence of mother and child in relation to breast feeding becomes apparent.

Happily, there is an awakening, slow though it is, as to the dire need of prenatal care. There is no earthly reason why more women of child bearing age should die from causes incident to pregnancy than from any other cause except tuberculosis, no other reason than an indifference or neglect on the part of municipalities. Maternal and infant morbidity and mortality dependent upon pregnancy, labor and puerperium are amenable to a decided reduction through a properly organized prenatal program, and not the least advantage of such procedure will be the saving of the lives and health of a larger number of mothers.

That the supervision of expectant mothers has a distinct bearing upon the possibility of increasing the number of babies who are breast fed has been shown in several studies conducted by the Bureau of Child Hygiene, Department of Health, City of New York, in which as a result of surveys made it has been found that while approximately eighty per cent. of mothers among the tenement population nurse their babies exclusively and while approximately sixty-eight per cent. of the babies enrolled at the baby health stations are breast fed exclusively and some thirteen per cent. partially, the number of infants who are entirely breast fed during the first

month of life, while under the care of a special corps of prenatal nurses, maintained by the Bureau of Child Hygiene, is approximately ninety-three per cent.

I desire to emphasize the importance of prenatal care, because in my opinion it forms the basis of every program for securing a larger number of nursing mothers. Every child has a right to be well born. A child's greatest asset is a healthy father and a healthy mother. Prenatal supervision carried out during many months of pregnancy, prepares the way for the good health of the mother, a healthy mental attitude towards nursing, good breasts and nipples, in other words, a comfortable pregnancy, a safe labor, and an uneventful puerperium. Sir Arthur Newsholme has said, "the mother is the main element in the environment of the infant." Since many of the conditions which surround the expectant mother and which maim or kill her are preventable, it behooves us for the sake of the infant, if not for the mother's sake, so to safeguard her health and wellbeing that she will be in a position to nurse her infant.

This is how the venerable Jacobi sums up the question. "What I want is that a pregnant woman should be in a condition to carry her fetus to its legitimate end in health and vigor and be able to nurse her infant. Every textbook talks to us of the inability of the woman to do so and indicates formulæ and trade shops and factories from which to graduate toothless young Americans. One hundred per cent. of our women, however, can be made to nurse, even the flower and fashion of the land. By breast feeding you will save a hundred thousand babies that now die or become invalids, from no other cause than unnatural feeding."

The care of the expectant mother has passed beyond the borders of municipalities or states. It has assumed national importance and has engaged the attention of the Government, to the end that ways and means are now being formulated to give federal aid to various states for the public protection of maternity and infancy and to establish minimum standards for such protection. An infant is always fighting with its back to the wall; but it is a brave little fighter holding on tenaciously until the reserves of care, attention and diet are brought to its aid. Yes, the most dangerous occupation in the world is that of being a baby. Less chance to live a week than a man of ninety, and to live a year than a man of eighty; less likely to survive its first year than an aviator who makes ascensions daily has of being alive at the end of the first year. Six times more dangerous than life in the trenches, do you wonder that it is necessary to surround it with safeguards against the many pitfalls which endanger it daily? And of these safeguards, the two most important are: 1, proper instruction and supervision of the mother who bore it; 2, every effort to provide it with what God and Nature intended it should have—breast milk. To nurse a baby is a mother's privilege and duty, to be nursed by its mother is a baby's birthright. Let there be no slackers in the great campaign of first aid in infant feeding, in the great cause for more and better babies—the instruction and supervision of expectant mothers.

DISTURBANCES OF THE HEART AND LIVER CAUSED BY LOW GRADES OF ASTIGMATISM.*

BY E. L. JONES, M. D.,
Cumberland, Md.

From the army which was recently drafted in the United States, a number of men who had been declared perfect on examination had to be dropped because of the fact that when they were put to the actual task of drilling and other physical exercises their hearts failed, and they became winded and exhausted, and yet showed nothing demonstrable on physical examination to explain why they were not as good as the others who stood up under similar conditions. In an article by George E. Pfahler (1), this class is characterized as the constitutionally inferior or third raters. While explaining nothing, cardiologists have termed this condition neurocirculatory asthenia, and as far as I am able to gather from my reading, they have nothing of value to offer for its relief.

For more than a decade I have observed cases of this type in civil life, whose number would run into hundreds, if limited to circulatory symptoms, and into thousands if many of the associated symptoms were the objects of consideration, which were largely or totally relieved by a thorough correction of errors of refraction. The title of this paper is intended to emphasize that any or all astigmatism must be corrected to the finest degree possible as to strength and axis of cylinder, else the small error remaining for the eye to overcome will still permit the continuance of symptoms. This does not mean that the other source of refractive eyestrain, hyperopia, does not play its part and need correction, which should be done; neither does it mean that myopia, which is not a source of refractive eyestrain, is not to be reckoned with. But associated with myopia and hyperopia of all degrees, and in cases of supposedly noncorrectible irregular refraction, there is usually more or less astigmatism, at times very difficult to establish as to exact amount and axis, unless the examiner is dominated by a fixed conviction that the symptoms point to astigmatism, and he will not stop until it has been worked out correctly.

I have found it best to presume that astigmatism is always present until its absence is indisputably proved, and in few cases presenting sufficient symptoms to call for examination can its absence be proved. It is said that in the early days of modern refraction, when visual acuteness was the only desideratum, that astigmatism under 1 D. did not amount to much; and without wishing to disturb the shade of the great Donders, it is stated he considered half a dioptre as the minimum of value. This is still largely true in non-presbyopes, from the viewpoint of attaining the sharpest vision possible; but where that search ends, the search for so-called eyestrain properly begins.

It would be desirable if a better term could be substituted for eyestrain, say eyestress, as the former term to the laity conveys the meaning of conscious effort on the part of the eyes, whereas it is most

often totally unconscious. Another error to be combated in the minds of the laity and general medical profession is that all cases of eyestress must produce either pain, discomfort or weakness of eyes, or some of the old classical symptoms of headache, nausea or nervousness. I wish to state with all emphasis possible that more people in my belief suffer from the eyes, than with the eyes, and my hope that the day will come when every patient affected with a persistent vertigo, pain or drawing in the neck or shoulders, unexplainable general fatigue, nervous depression, gas in stomach, cardiac asthenia, or cold, clammy feet, will be referred to the most painstaking oculist available, for that careful search for astigmatism, either alone or buried under a smaller or larger amount of far or near sightedness, the correction of which usually brings relief after enough time elapses to permit the dying out of these vicious symptoms after removal of their cause. Not to inform patients of this necessary lapse of time is likely to cause them to discard our efforts as futile, bringing loss to themselves and disrepute to their oculist.

During the earlier years of my career, following the lead of such authors as I had been able to study, I held the belief that astigmatism not reducing vision in presbyopes, especially advanced presbyopes, was of little or no consequence, and that presbyopia when fairly complete had so set the accommodative mechanism that eyestress could not result. To me the doctrine is now anathema maranatha; one that should be utterly stamped out, regardless of any theoretical bolstering up, when cold facts prove how much somatic disturbance may come from astigmatism, especially of low degree, at advanced ages.

As some of the tenets set forth in this article, together with their attempted explanation, will no doubt challenge the credulity of some and the antagonism of others, it is desirable to go into certain details that would otherwise seem unwarrantable. Lieut. Col. R. H. Elliott, in a paper on errors of refraction says (2): "Let each one tell what they actually do in their practice and not what they would like to do, or what they would like others to think they do"; and further on quotes Kipling's lines:

"But each for the joy of the working,
And each on his separate star,
Shall draw the Thing as he sees It,
For the God of Things as They are."

In the first place, the fitting of glasses, aside from simple presbyopia, should be considered as much a part of the practice of medicine, as diagnosing diseases, prescribing drugs, or doing minor surgery. In many patients the issues of being able to enjoy good health and successfully pursue happiness, are as much dependent on a proper refraction as the outcome of some of the most ambitious operations of major surgery, where the issue of life itself is not involved. But in the estimation of the laity, and sometimes of the medical profession, getting glasses is merely a matter of purchase with the purchaser as the chief arbiter of what is to be done.

In late years much stress has been laid on disturbances of the ductless glands, in the practical investigation and application of which Dr. Crile has

*Read before the American Academy of Ophthalmology and Otolaryngology, Cleveland, October 16, 1919.

played a prominent part. In his masterful contribution on the kinetic drive he has shown the effect of infections, of loss of sleep, and great fear or long continued anxiety or depressing emotions, and as the ductless glands and sympathetic nervous system are the drivers of the heart, whatever stimulates or inhibits these must bear out its effects on the heart. To his list of disturbers should be added another, as potent as any, and probably more common than all of the others, viz., eyestrain. Since the promulgation of our present day beliefs as to hyperthyroidism and hypothyroidism, the similarity of these in many respects to long continued eyestrain has forcibly struck me, and caused a belief that the thyroid was being held responsible for a number of sins chargeable to the prime cause of eyes under stress, although they work their harm by causing secondary derangement of the ductless glands, chiefly the thyroid, and probably the adrenals and pituitary. These cases early in their evolution probably first pass through a short phase of hyperthyroid symptoms, as in the case of a girl of twelve who came in while this paper was being written. She came on account of mild discomfort in her eyes with nervous excitability. Her pulse on admission, after a short conversation on commonplace things, was 136; after sitting an hour waiting on cycloplegic drops, it was 120, and pounding like a triphammer. Her mother had noticed this in her sleep. The more common cases have passed from hyperthyroid to hypothyroid symptoms of nervous depression. In a recent case in a young married woman apparently in the best of health the pulse was 64. She had been sent by her physician to seek relief for headaches, and inquiry showed that she also had dizziness, pain in the neck and shoulder, was nervous, depressed, tired, easily winded, and had a palpitating heart, the first sounds of which were rather faint, but no discomfort or weakness about the eyes. She had undergone a thyroidectomy seventeen months previously. When she came back five weeks after having her astigmatism corrected, she was already beginning to feel better, her pulse was 76, and the heart sounds were distinct.

A misconception universal among the laity, and general among physicians, is that eyestrain only comes from the near use of the eyes, and is dependent on long hours of close work, and should therefore find its chief sufferers among bookkeepers, students, stenographers, and seamstresses, and should be relieved by giving up these various callings for a life in the open. A more pernicious and misleading doctrine was never promulgated. The majority of the patients observed were the wives or daughters of farmers, miners, carpenters, railroaders, and mill workers, who gave relatively more time to domestic duties and less to reading or needle work than did those who call themselves the intellectuals.

Women are more frequently subject to symptoms of eyestrain than men, notably in regard to nervousness, the neck and shoulder pain or drawing, and cold feet. The man more often controls his nerves. But when a man does have the neck and shoulder pain, which is a liver symptom, or cold feet, a heart symptom, he usually has them badly. It is a com-

mon occurrence to have a well developed husky farmer or mechanic come for some minor discomfort of the eyes, and reveal, upon inquiry, that he is easily tired and winded by a short amount of physical effort, and has been puzzled as to why it should be; or has been taking general or heart tonics without avail. These are often presbyopes with reading glasses or bifocals giving perfect vision, but poor satisfaction. A recent illustrative case occurred in a man of forty-eight, healthy and robust in looks, leading an active outdoor life, who complained for many years that his eyes burned, itched, reddened, and pained from bright light, that things would blur after a short time, and the eyes would water too readily. He had frequent headaches, occasional sick headaches, was very dizzy, had severe neck and shoulder pain, was easily tired and winded, with palpitation of heart, and his feet and legs were cold. He stated that he frequently bandaged his knees to keep them warm. The glasses he had been wearing were lost when an attack of dizziness struck him while he was driving, and the car with himself and wife rolled down a bank. This patient had a common condition that may never appreciably blur vision, but is prolific of eyestrain—mixed astigmatism of low degree. Roby and Boas (3) gave the results of studying a series of cases of neurocirculatory asthenia at Camp McClellan, in which they concluded that exercises accomplish little or nothing toward overcoming the weakness, but are of great value in establishing the diagnosis. They refer to accompanying dizziness, and emotional stress. In discussing this paper, Sir James Mackenzie, of London, spoke of some of these patients having cold extremities, at times being flushed. It is common to have some patients with eye symptoms complain of hot burning feet, when under similar conditions others complain of cold.

Friedlander and Freyhof (4) and Barringer (5) emphasize the associated symptoms of dizziness, nervousness and cold, clammy extremities, and the fact that many of the patients were below par since childhood. Other observers (6) started out with a belief that statistics would show the condition more often associated with enlarged thyroid, but the result, as far as any differences went, was in favor of a greater prevalence where there was no thyroid enlargement. To show that their clinical description conforms to the types of cases which have been relieved by correcting astigmatism carefully, several quotations will be made. "The symptoms were precordial pain with dyspnea and palpitation on moderate exertion, such indications of vasomotor instability as dizziness, flushing and fainting, and a variety of other complaints, all pointing to a state of excessive reaction of the nervous system to psychic or physical strain.

"Dyspnea, palpitation, and precordial pain are taken as cardiac symptoms. Dizziness, flushing and fainting are taken as indications of vasomotor instability. Mental irritability, emotionalism, apprehensions, depression, excitability and exhaustion, and shakiness after exertion or excitement, were all grouped under the heading of nervous instability."

One of the outstanding clinical features in both

conditions, though this is more especially true in neurocirculatory asthenia, is the multiplicity of subjective complaints, and the paucity or absence of objective evidence. So it is mainly on symptoms and not on signs, that the diagnosis rests. And the special characteristic of the symptoms is the wide field they cover. It is not only the cardiac or the vasomotor or the nervous system which is at fault, but all three together. "What has been termed the symptom complex, that is, an association in the same individual of symptoms of cardiac, vasomotor and nervous instability, is as often seen in nonthyroid as in thyroid cases."

These cases are not rare in civil life, but when looked for, will be found rather commonly. When it is considered to what extent the patients may be relieved by a correction of all the errors of refraction, and proper glasses worn all the time for a long enough period, it makes the remark of one of America's foremost surgical ophthalmotorhinologists publicly expressed some years ago that the refractionists claim to cure everything from headaches to hemorrhoids with glasses, seem as full of truth as of sarcasm, for it can safely be said that by this means many ills from vertigo to cold feet are permanently eradicated.

In addition to the hyperthyroid and emotional stress hypotheses, Major Carroll (7) seeks to establish, as have also some of the other authors quoted, chronic infections as a cause of neurocirculatory asthenia. There is no doubt that all of these play a contributing part in a lowered resistance caused by some previously acting cause. Few things of slow development come from a single condition, but a combination of conditions and circumstances, and sudden collapse of a heart or a mind is more often due to long and slowly acting, unrecognized undermining, than the immediate precipitating cause. If the matter could be tested out, it would probably be found that a large proportion of shell shock cases, as well as the neurocirculatory cases, had been undermined by a long acting eye strain. As corroborative of my assertion that eye strain symptoms affecting the heart are not more common among close workers with the eyes, the following quotations from F. G. Hein (8) are based on studies of neurocirculatory asthenia at Camp Sherman: "Three hundred men returned to the development battalion from the various line organizations because of complaint of heart trouble throw some light on this problem. The men passed apparently normal, were placed in organizations, found unable to drill, rejected as unfit for military service, and referred to the development battalion. It is interesting to note that 154 have had symptoms for five years or more, some insisting that they have always had distress. As shown in Chart I, the largest number of cases occurred among farmers, with laborers next, the two classes forming fifty-six per cent. of the total. The clerical positions came next, with seventeen per cent. Giddiness, present in 242 cases, was the most common symptom; on prolonged or sudden severe effort, dyspnea occurred in 239 instances. A hike, or double quick time, sent these men out of formation in short order."

An impressive illustration of the effect of correcting astigmatism in these heart cases, and the permanency of the relief, occurred some years ago in Mr. H., a man of athletic build and exemplary habits. He was raised on a farm and worked at milling when the farm work did not demand his attention. After manhood he qualified for, and entered the legal profession. After getting into his early forties his heart began to functionate poorly, and anemia and morbid fears developed to the extent that for several years he never began a day with any feeling of assurance he would live through it; did not dare to lock a door for fear he would drop dead and some one would have to break in the door; dreaded to undertake the simplest duties of his profession, for fear he might not live to finish them; if he started across the street to the barber shop, he wondered if he would live to get there, and seated in the chair he would think "this barber will look up, and when he looks down again, he will be looking at a dead man." His home physician could make out no organic heart trouble, and finally referred him to Dr. Thayer, in Baltimore, who also pronounced him free of any organic heart trouble on three separate occasions, and advised him to return for a season to the simple rural life, living in the open, attending as hostler to his pony and other tasks. He also went to Florida for a few months as a relaxation and diversion. His eyes had never given him the slightest trouble in feeling or function until at the age of forty-five he began to have considerable trouble skirmishing for lights and focus; in other words, he had normal presbyopia.

On May 13, 1910, at the age of forty-six, he applied to me for optical aid. There were no symptoms of eye discomforts or headaches, he simply had to hold the print off, and then could not see the two smaller blocks of Jaeger types. An examination showed a considerable amount of mixed astigmatism; the cycloplegic drops were used, and as is generally the case, eliminated a considerable part of the minus element. I had for some years been convinced of the disturbing action of astigmatism on the heart, especially as exemplified in chronic cold feet in women of a most robust type, as well as delicate looking persons. I told him: "Mr. H., I think we have the nigger in the woodpile that has been causing all your heart trouble." Such proved to be the case, for with the constant wearing of glasses, to which presbyopic addition was subsequently made, he soon threw off his disabilities, and he has remained well to the present time. Last year he applied for life insurance, and the company held up his application because of a loss of weight of twenty pounds from his erstwhile average, and asked for an explanation. His answer was that the country was at war and long on lawyers and short on farmers, so he went back to the farm and worked off that twenty pounds. They gave him the insurance. The anemia referred to has often been noted, and it is no rare thing to see it vanish as rapidly after eye correction, as it does in other cases when the cause, such as malaria, sepsis, or hookworm is removed. Likewise, patients under their normal health weight, often gain flesh with the same rapidity. Where the anemia and loss of

weight have been marked, it is sometimes hard to recognize the patient as the same person after a few months. This is because the nutritional system is upset by the disturbances of the liver.

Dr. Lyster says (9): "After studying the subject in the military camp at Camp Custer, Mich., I am convinced that this syndrome, which was first described by Da Costa, during the Civil War, and by the French, English and American physicians during the recent war, is not a cardiovascular disturbance primarily, but the disturbance of the autonomic and sympathetic nervous systems." Dr. Bliss says, "An internist in France insisted that all these cases were caused by a hyperthyroid condition, while I insisted that relatively few were due to a hyperthyroid condition. There are constitutional cases. You cannot make soldiers out of these men. No form of treatment changed these individuals, either physically or mentally, so as to enable them to be good soldiers. The important point to recognize is that they were constitutionally inferior, and not capable of such restoration as would make them efficient men." Dr. Neilson says, "When the first soldiers were being examined in St. Louis, I went so far as to accuse some one of giving these young men thyroid extract. We put many of them into the army. Some came back with neuritis, some with hyperthyroidism, and some with constitutional disorders. Later I decided to put these individuals into limited service, but I found that the limited service men worked just as hard as the regular soldiers, so we decided to send them back to their own work. We do not know what is wrong with these people, or that there is anything wrong with them, but I believe there is something behind it. I am not so enthusiastic as to attribute all these disturbances to the ductless glands."

Time and again I have observed patients of this type who applied either for minor discomforts about their eyes, or in their opinion, things which might be due to eyes, when inquiry revealed that they were either tired, or became easily exhausted, and became dyspneic from the slightest exertion, when their appearance indicated they should measure up to full standards of strength. Not a few have come for aural troubles, and in a purely accidental way, have spoken of how tired they always were, and how quickly they became exhausted, and had no complaint whatever as to comfort or endurance of vision, and yet a painstaking correction of refractive errors, often exceedingly small and hard to find, would relieve them of the asthenia. In many of these cases vision was absolutely normal, and the eyes rejected all glasses indicative of ametropia; but the use of a cycloplegic would often reveal a surprising amount of concealed error, even up to the age of fifty or beyond. On the other hand, the error may be so slight that vision under a cycloplegic is normal, and apparently no error to tests made with no more than ordinary care, but by taking sufficient pains, a low cylinder can be definitely proved to be called for and in this class of cases some of the most phenomenal results have been achieved.

A few years ago a civil engineer, aged thirty, complained of great fatigue in the presence of a

railroad official, who had, by accident, fallen under eye treatment which relieved him of these mysterious fatigue symptoms, and was told to have his eyes investigated. He had in addition to a general fatigue beyond reason, several other symptoms of eye strain, and as usual no importance was attached to the fact that the vision was supernormal and tests for error repudiated, but when under a cycloplegic vision was 20/16, and all glasses for a time rejected, things began to get interesting. By much persistence, the presence in one eye of one quarter of a diopter of astigmatism with axis at off angle, and the other a like astigmatism with equal spherical error, was finally established. It was explained to him he must wear glasses all the time. Some months later, he was observed to be much improved in appearance and weight.

Detractors of the value of exact correction of errors say that much of the good observed is due to suggestion on the part of an enthusiastic refractionist, and expectancy on the part of the patient. This criticism is readily answered by the havoc played with many patients who have been relieved, when one cylinder gets thrown a few degrees off axis, and the patient still thinks his glasses the same. Such patients will sometimes say, "I cannot wear my glasses, and I cannot go without them." In older days with flat lenses, this often came about by a glass falling out and being put in backward, or having the frame bent; in latter days, by accidental rotation of a round lens. Another source of trouble is replacing lenses from the broken pieces, when either the axis of a recognized cylinder is slightly misplaced, or a weak cylinder, in combination with a strong spherical, is altogether overlooked. An illustrative case is a man of forty, of athletic proportions, who came six years ago for sundry vague complaints about his eyes of several years' duration. Inquiry revealed that he was always tired, got no relief from vacations, and had to force an interest in his business. Eyes tested normal, but under a cycloplegic, right showed one and a half spherical with one quarter cylinder axis 135, and left one spherical with +0.62 cylinder axis forty-five, which were given for constant wear. After the usual difficulty of getting used to them for distance, he was relieved in body and mind, and got on well for two years. His old symptoms then returned, and he came for reexamination. It was observed he had other glasses, which he said were made on the formula of those first worn. Inspection showed the cylinders had been omitted, and when glasses were supplied by correct formula, he became well again. At the expiration of another year, he indulged in the new-style round lenses, and symptoms again drove him to report for relief, when lenses were found correct, but axis of cylinders reversed. They were set right and marked, and no trouble has been reported since. The majority of these patients with muscular asthenia, neurasthenia, and psychasthenia, if questioned, will also be found to present evidences of neurocirculatory asthenia, as exemplified by their being easily winded, with palpitation of the heart from slight effort, clammy hands and feet, and the other symptoms detailed in the previous quotations.

These conditions are much more common among women than among men, and in a regiment of Amazons a large proportion would drop out when put to drilling. To see these Amazon women who are always dead tired, with pain or drawing in the neck and shoulders, easily winded, with fluttering hearts, gas in stomachs, and cold, clammy extremities, measure up to their looks after having an astigmatism corrected, is more suggestive of a play that is staged, than the realities of life. They will often say on presentation, that the worst of it is, they look so healthy and strong, that no one will believe how tired they are, and how miserable they feel. On the other hand, some of the opposite type look as miserable as they feel, and in such the improvement in looks, color and weight may be observed *pari passu*, with their feelings. One not infrequent afterresult is that those who had settled down into a condition of confirmed celibacy feel so buoyed up in health and spirits, that they view life from a different angle, and embark on the sea of matrimony. Nearly two decades ago I began to note, more frequently in women, in cases of eyestrain, the presence of a pain or pulling in the neck, or shoulders, or between the shoulders, not rarely running out into the arm, or even to the finger tips, accompanied by a tingling or numbness in the arm which has been pronounced by some as neuritis. This pain also in some instances runs from neck to ear, or continues on from ear to eye. However old, or well known this symptom may be to others it is only in very recent years I can recall having seen any reference to it in such promiscuous articles as I am able to peruse, as for instance in the report of Major Newcomb (10), of the Army Service, where it is referred to as the checkrein symptom.

It is not mentioned by Stephenson (10), who covered the literature of the subject up to date of its publication four or five years ago. In seeking its explanation, I came to the conclusion it was a distress signal of the liver; the older works on medicine abounded in references to pain in the shoulder as a symptom of liver disease. Anatomists tell us the parenchyma of the liver has no sensory nerves, but only sympathetic fibres, but that these sympathetic fibres anastomose with the spinal sensory nerves, and it is most likely by this means the protest of the liver is registered against a factor disturbing its normal functioning. By this same inhibition of hepatic functioning is also plausibly explained the flatulence so commonly due to eyestrain in elderly people of both sexes, but probably more common in females. In presbyopes, who have obtained age glasses and found them unsatisfactory, it is one of the very commonest of symptoms, and usually diminishes or goes away when the causative astigmatism is properly corrected by glasses worn absolutely all the time except when patients go to bed to sleep. It is likewise my belief that the headaches and sick headaches recognized for two generations as coming from the eyes, and the vertigo equally common, but not so generally admitted as an eyestrain reflex, are directly due to the inhibition of hepatic function by eyestrain, and are consequently exactly the same in nature as the

acute bilious attacks due to other transient causes, putting the liver out of commission for the time being, such as getting overheated on a full stomach. Inasmuch as Dame Nature finds relief from emptying the stomach under these conditions by vomiting, she tries the same tactics in the headaches due to eyestrain, thus explaining the nausea or vomiting of sick headaches.

On February 15, 1910, a woman aged thirty-nine, came to me because of sundry discomforts in the use of her eyes, and inquiry revealed she had for several years suffered from a severe pain under her right shoulder blade, which remained, much to the perplexity of her surgeon, after he had removed a large number of gallstones by operation, other symptoms due to gallstones having vanished. I remarked that I had for some years been interested in the similarity of certain symptoms arising from gallstones and eyestrain and hers would be a good case to try them out separately. She showed some manifest error but much more under a cycloplegic, and surprised and pleased her oculist by wearing the full correction without the usual protests about the annoyances of breaking the eyes to the glasses. When commended for this, she said the glasses were doing too much good to complain about. That before, life did not seem worth living; the pain was gone, and even her children noticed a change.

In discussing the origin of vertigo, the older medical works had much to say of plethora, and disorders of the stomach and liver, while the latter day works speak of high blood pressure, arteriosclerosis, and aural troubles. It seems to me that in late years the current literature on vertigo from aural origin to that from ocular origin is about in the proportion of an unabridged dictionary to a pocket edition, while from my observations the reverse is really the case. Patients with hardening of the arteries and vertigo to the point of complete incapacity for the ordinary tasks or pleasures of life, have been relieved of the vertigo by correcting astigmatism, often buried under a farsightedness for which they had for many years worn bifocals, or in those having in the glasses they had been wearing an astigmatic recognition which was not correct as to strength and angle. By reason of the abundant literature on aural vertigo, a number of these cases have been referred for ear treatment, but cured by attention to eyes. One old lady of sixty-seven had suffered severely from vertigo for thirty years, so much so that her physician considered it Ménière's disease; she was wearing spherical bifocals. On correcting a moderate amount of complicating astigmatism, she soon became entirely free of her dizziness, and wrote, a few years back, that she had had only one bad spell in three years, which she attributed to overloading her stomach during a hot spell of weather.

In numerous instances patients have refused to believe the constant wearing of glasses necessary, usually stating they could not wear the glasses, enduring their symptoms months or years before settling down to make themselves carry out instructions which brought the desired relief.

When we consider what a transformation in one's

life the uprooting of a small astigmatism can make, we may well conclude that one in the search for it should have the convictions of Columbus that there is something worth searching for, and in finding it, if need be, the patience of Job.

SOME PRACTICAL CONSIDERATIONS OF SQUINT.*

BY JOHN H. DUNNINGTON, M. D.,
New York.

Looking at an object with the two eyes open a normal person fixes the same object with both eyes. A squint is present when it is possible for him to fix on an object with only one eye at a time. Divergent squint is the condition when, with both eyes open, one eye is looking at an object and the other one is turned outward, i. e., there is an actual divergence of the visual axes of the two eyes. The deviation is called convergent squint when the squinting eye is turned inward. Also the condition of upward squint and downward squint designates the position of the squinting eye. Therefore it can be said that the character of the squint depends upon the position of the nonfixing eye.

Normally the two eyes are capable of being simultaneously moved in any direction, i. e., up, down, right or left, but in addition to these excursion movements, the eyes perform two very important movements, that of divergence and that of convergence. Divergence of the eyes is produced by simultaneous outward rotation of both eyes. This act of diverging the visual axes is probably produced by simultaneous equal relaxation of both internal recti muscles accompanied by equal simultaneous contraction of both external recti. There is a definite cerebral centre to govern divergence. Neurologists are loath to admit the existence of such a centre, but clinical evidence strongly supports the contention of ophthalmologists that one exists. Dr. Alexander Duane, who has made a very thorough study of the ocular movements, is of the opinion that this centre is in close proximity to the nuclei of the sixth nerves which are situated on the floor of the fourth ventricle near the median line. Errors of diverg-

ence result from an overaction or an underaction of this centre.

A divergence excess is therefore present when the eyes possess an abnormally great power of simultaneous outward rotation. This is a common condition and is the starting point for many divergent squints. It is impossible to inhibit the over-exacting centre, so we have to adopt the measure of weakening the acting muscles. This is done by tenotomies of the external recti muscles. The use of glasses to correct a squint due to divergence excess always results in failure. Operative treatment is the only cure for such cases.

The opposite condition, that of paralysis of the power of divergence, affords a more interesting picture. In this condition there is usually a sudden onset of a distressing double vision (diplopia) for distance, but no diplopia for close range. That the patient has usually detected this is evidenced by his statement that he has diplopia when he looks at a distance, but can see to read without difficulty. There is a marked convergent squint as the patient looks at a distant object, but none as he fixes on a near point. Both eyes can move outward in a perfectly normal manner and there is no limitation of motion of either eye in any field. This normal outward rotation of each eye would differentiate it from an external rectus paralysis, with which it is commonly confused.

Dr. Wheeler, with whom I am associated, reported the following typical case:

CASE.—In February, 1918, a man, W. J., twenty-five years of age, called at the New York Eye and Ear Infirmary saying that on August 1, 1917, while digging a ditch his vision became suddenly confused and since that time he had seen double at a distance. He was in the hospital three months but left unimproved. Vision was normal in each eye; nothing pathological could be found in the interior of either eye. There was no limitation of motion of either eye in any field. There was diplopia at a distance but none for near range. Pupils reacted to light and accommodation in a normal manner. The urine, blood and spinal fluid Wassermann were all negative. In this case paralysis of divergence probably resulted from hemorrhage into the divergence centre while the patient was under physical exertion.

The pathology of such a paralysis is doubtless a lesion in the centre. The most likely causes of such a localized disturbance are lues, cerebral tumor, multiple sclerosis and tabes, but often it is impossible to find any etiological factor. The prognosis for recovery from the paralysis is bad, but usually relief from double vision is achieved by suppression of one of the images. A constant convergent squint is the final result. The knowledge of the existence of such a condition is of importance in that its presence means a definite cerebral lesion and warrants a most thorough examination. It may be the precursor of a much more serious cerebral disturbance.

Convergence is the other unparallel movement which the eyes are capable of performing. Both internal recti muscles contract at the same time and to an equal extent, thereby causing both eyes to be

*Presented before the Richmond County Medical Society, March 10, 1920.

turned inward. The act of convergence is also controlled by a cerebral centre. This centre may be overactive or underactive.

Convergence excess is therefore produced by an overacting centre. This frequent anomaly of convergence is responsible for many convergent squints. It is often associated with hyperopia (farsightedness). It is in these cases that glasses do the most good toward correcting the squint.

With an underacting centre we get an insufficient power of convergence. This inability to converge may vary in degree from a slight underaction to a complete paralysis. Many divergent squints result from untreated convergence insufficiencies. There are many causes of convergent anomalies besides refractive errors, but we cannot consider them at this time. However, it is important for us to remember that disorders of convergence produce squints. A convergent squint may be the result of an excess of convergence, or a divergent squint may come from an inability to converge the eyes. This converging power must not be confused with the power of internal rotation. A patient may have normal power of turning each eye in separately, i. e., the power of internal rotation be good in each eye and still be unable to converge. This fact clearly demonstrates that the convergence movement is a separate and distinct function from that of simple inward rotation.

A squint can also be caused by a paralysis of one or more of the ocular muscles. The character of the squint depends upon what muscle is affected. For example, if the right external rectus is paralyzed the right eye will turn inward. There will be limitation of movement of the right eye outward because the muscle which moves that eye out is paralyzed. In paralytic cases, unless they are of congenital origin, the onset is usually sudden. The patient complains of diplopia with its attendant nausea and confusion. There may or may not be an evident squint. A history of the sudden onset of double vision is most suggestive of an ocular muscle paralysis.

Consideration of the etiology of ocular palsies is of interest to the general physician. Syphilis is the most common cause. It is not an uncommon thing in fracture of the base of the skull for a patient to get an ocular muscle palsy from injury to one of the nerves as it emerges from the base of the skull. It occurs as an occasional complication in influenza, diphtheria, whooping cough and in the acute exanthematous diseases. Congenital paralyzes occur not infrequently, and often a case of supposed torticollis is due to congenital ocular muscle paralysis.

The treatment of these acquired paralytic squints is largely that of the underlying cause. If syphilitic in origin give energetic antisyphilitic treatment. In the traumatic cases it is often wisest to do nothing until nature has had time to repair the damage by regeneration. Operative intervention is indicated in the congenital types, but in the acquired paralytic squints give the patients the benefit of thorough treatment before considering operation.

PSEUDOSQUINT OR APPARENT SQUINT.

Having considered the etiological factors in actual squint, we pass now to a most interesting con-

dition, pseudosquint or apparent squint. It is common among children and I believe fully one third of the cases of supposed convergent squint in children belong to this category. The child appears to have crossed eyes but the examination shows no evidence of squint. What then is present? The child's nose has a broad and flat appearance, the bridge of it is underdeveloped. The skin of the nose, instead of being tightly adherent to it, is loosely attached; except at the inner canthal ligament. This laxity of attachment may permit the skin to hang in a vertical fold producing a condition known as epicanthus. The inner canthi are farther apart than normal. This increased distance between the inner canthi is caused by two factors. First, the looseness of the attachment of the skin to the underlying bones and second, the underdevelopment of the bridge of the nose. The position of the eyeball in the orbit is normal and the distance between the nasal orbital walls is no greater than normal. This loosely attached skin therefore covers a part of the nasal portion of the sclera on either side, giving the patient the appearance of having a convergent squint. Such a facial appearance is a characteristic of the Mongolian race. We are all familiar with the peculiar appearance of a Chinaman's eyes. He has this underdevelopment of the nasal bridge which gives him an apparent convergent squint. His nasal bridge never develops so he keeps this condition throughout life. The ordinary child, however, does develop a bridge to his nose and as this development proceeds the skin is drawn inward and forward. In this way the deformity is corrected. A cure then is simply dependent upon full facial development. I cannot stress too strongly the importance of recognition of this condition. The failure of physicians to appreciate this facial change has led to the very widespread belief that a squint will correct itself. I have known of several cases where glasses have been prescribed to correct the squint when only this apparent condition existed. It is not always easy to differentiate these two conditions especially in very young children but a careful examination will definitely establish the diagnosis. The importance of differentiating the actual from the apparent squint is evident, as actual squints demand early treatment and apparent squints need none. Do not tell the parents the child will be all right when he grows up unless you are positive it has only an apparent squint.

The reverse condition of apparent divergent squint is occasionally seen in persons who have a particularly high, narrow nasal bridge. In these cases the skin is stretched tightly over the bony structures and more than a normal amount of scleral tissue is exposed on the nasal side of the limbus. This demands no treatment and is rarely marked enough to be disfiguring.

GENERAL CONSIDERATIONS.

There are certain features of squint cases which are of particular interest to the general physician. He is the man who usually is first consulted about this deformity. What should he do? It is his duty to advocate early treatment in all his squint cases. Do not accept the responsibility of postponing treat-

ment. Put that up to the oculist. The chief reasons for advocating very early correction of the squint are three in number. The first is the loss of vision in the squinting eye. Amblyopia exanopsia as this deterioration in sight from disuse is called, ensues very rapidly in young children. Some oculists contend no such loss in sight can occur yet the clinical evidence strongly indicates its existence. Worth, an eminent English ophthalmologist who has devoted a great part of his time to the study of this problem, says "a child with good vision in each eye who develops a constant unilateral squint at the age of six or eight months will in the absence of proper treatment become rapidly blind in the squinting eye. This loss of vision in the infant's deviating eye is so rapid that the power of central fixation is often lost within eight to ten weeks." The older the child the less rapid is the loss of vision. After six years of age amblyopia exanopsia rarely takes place to any marked extent. Acquired amblyopia is a true loss of vision, not a failure of function to develop. Not every case of squint develops this amblyopia, for in some we see first one eye fixing and then the other. It is in the unilateral squint that this gradual loss of vision does its greatest harm.

There is another or second important reason for the early correction of the squint. A permanent loss in the ability to use the two eyes together occurs in practically every squint of long standing. Binocular single vision is affected by a psychical blending of the two sets of visual impressions into one composite picture. According to Worth, the power of fusion of the images of the two eyes begins development very early (by the end of the first year) and is considered complete by him at the end of the sixth year. It is impossible for the mind's eye to fuse the images of the two eyes into one when a squint is present, therefore to him everything appears double. Children readily overcome this double vision by ignoring the image of one eye. This necessitates the using of only one eye at a time. Therefore, unless the squint is corrected early, the ability to use the two eyes together is lost and never regained. With only monocular vision it is impossible to judge distances accurately or to appreciate fully the sense of depth. The possession of this faculty of binocular vision was considered important in the army air service. Without it no one could qualify as a flier, for in aviation accurate estimation of distances is often essential.

The third or cosmetic reason for the early correction of squint is the one which usually brings the patient to consult an oculist. The unfortunate cross-eyed child is greatly handicapped. Children poke fun at him; call him "Mamma's crosse-eyed baby." He is very sensitive about it. He becomes shy and backward in school. He avoids his playmates, and becomes of a sullen, disagreeable nature. Early correction of the squint removes the possibility of such a change occurring in the child.

To summarize, then we should advise early correction of squint, 1. To prevent amblyopia exanopsia (loss of sight from disuse. 2. To preserve the ability to use the two eyes together. 2. To remove the deformity which is a genuine handicap to the development of the child's mind and body.

TREATMENT.

How should a squint be treated? Every case of squint should receive a most careful eye examination. The first duty of the oculist is to find out what is causing the squint. If the refraction of the eye be a factor, correct that, but most ophthalmologists make the mistake of considering every case of squint one of only refraction. Do not tell your patients with squint that it is simply a matter of glasses. Too many other factors have to be considered to warrant such a broad statement. Many squints do not require glasses and some are even made worse by the use of them.

If the squint is due to a syphilitic muscle paralysis glasses will not help but antisyphilitic treatment will. In every case of squint a most careful search for the cause of the actual condition should be made and your treatment be directed toward the correction of the productive factor. The nonoperative treatment should therefore be strictly causal in nature.

Many cases require operative interference. The age at which operation should be advised is an important consideration. There is a widespread belief among practitioners and oculists that it is unwise to operate on any patient with squint under ten years old. Parents are therefore continually being told to wait until the child is older before thinking of operation. We have already considered the great harm resulting from such neglect. Operative measures are indicated as soon as you have satisfied yourself that nonoperative treatment will not cure the patient. It does not matter whether the patient is two or twenty, if operation is indicated, operate. Good results follow early correction. Operate when necessary to correct the squint regardless of the age. The youngest patient I have heard of was two years old at the time of operation, but I see no reason why if the case required operation it could not be done at an earlier age than this.

We have in general two operative procedures: 1. A weakening of an overacting muscle; 2, a strengthening of an underacting muscle. The tendon of the muscle at its insertion into the globe is severed either partially or completely to effect this weakening in the tenotomy operation. There are two ways of increasing the action of a weakened muscle; first, the tendon can be shortened or resected, second, the insertion of the muscle can be carried further forward (near the limbus), in other words, advance the insertion. It is quite often necessary in squints of long standing to combine a resection of one muscle with a tenotomy of its antagonist. Cocaine anesthesia for these operations can be effectively used on young children. Local anesthesia has to my knowledge been used with perfect success in a patient six years old.

In conclusion let me again call to your attention these considerations:

1. That the existence of divergence as a separate and distinct function from that of external rotation is an established fact. Also that convergence is not simply an act of internal rotation but that it is a distinct entity. The performance of these movements are controlled by cerebral centres.

2. Pseudosquint is a common condition, the ex-

istence of which is responsible for the very strong belief that a squint corrects itself in time.

3. An actual squint demands early correction to save the vision in the squinting eye, to preserve the ability to fuse the images of the two eyes, and to remove the deformity which is a great handicap to the child's progress.

4. Operate when indicated regardless of age. No bad effects result from early operation. Much is lost by waiting.

80 WEST FORTIETH STREET.

MEDICAL MEN IN THE AMERICAN REVOLUTION.

The New York Campaign of 1776.

BY LOUIS C. DUNCAN, M. D.,
Washington, D. C.,

Lieutenant Colonel, Medical Corps, U. S. Army.

(Continued from page 416)

6.—RESOLVED:

That every director of a hospital possesses the exclusive right of appointing surgeons and hospital officers of all kinds, agreeable to the resolution of Congress of the 17 July, in his own department unless otherwise directed by Congress. That Dr. Stringer be authorized to appoint a surgeon for the fleet now fitting out on the lakes.

That a druggist be appointed at Philadelphia whose business it shall be to receive and deliver all medicines, instruments, and shop furniture for the benefit of the United States. That a salary of thirty dollars a month be paid to said druggist for his labor.

"Congress proceeded to the election of a druggist and the ballot being taken, Dr. Wm. Smith was elected."

This druggist appears to have been a storekeeper, or medical supply officer. The medical committee of Congress seems to have done the purchasing.

GENERAL GREENE'S LETTER TO WASHINGTON.

Camp at Long Island, *August 11, 1776.*

7.—Dear General:

There is no proper establishment for supplying the regimental hospitals with proper utensils for the sick; they suffer for want of proper accommodations. There is repeated complaint on that head. The regimental hospitals are and ever will be rendered useless, nay grievous, unless there is some proper fund, to provide the necessary conveniences. The general hospital cannot receive all the sick: and those that are in the regimental hospitals are in a suffering condition. If this evil continues, it must injure the service, as it will dispirit the well, to see the sick suffer, and prevent their engaging (enlisting) again, upon any conditions whatever. Great humanity should be exercised toward those indisposed. Kindness on one hand, leaves a favorable and lasting impression; neglect and suffering on the other, are never forgotten.

I am sensible there has formerly been great abuses in the regimental hospitals, but I am in hopes men

of better principles are elected to those places, and that the same evils will not happen again. But the Continent had better suffer a little extraordinary expense, than the sick should be left to suffer, for want of those conveniences so easily provided.

I would beg leave to propose that Colonels of regiments be allowed to draw monies, to provide the regimental hospitals with proper utensils; an account of the disbursements, weekly or monthly, to be rendered: This will prevent abuse and remedy the evil.

Something is necessary to be done, speedily, as many sick are in a suffering condition.

The general hospital is well provided with everything and the sick are very comfortable. I wish it was extensive enough to receive the whole, but it is not.

I am, your Excellency's most obedient servant,
NATH. GREENE.
August 13, 1776.

8.—"Doctor John Morgan, Director General of the Hospital, attending, was admitted. He informed the convention that General Washington had directed him to have all the sick removed to proper places out of such parts of said city as are closely built and inhabited; that a list of houses had been handed to him for that purpose, by private persons, but that as he is a stranger, and does not know what particular persons might be proper to be exempted, and, therefore requests the direction of the convention in the premises.

Resolved that his Excellency General Washington be and is hereby empowered to apply the following houses, to wit:

Mr. Aplethorpe's,

Oliver Delancey's and

Robert Bayard's at Bloomingdale.

William Bayard's, at Greenwich.

Mr. Watts', near Kipp's Bay, [East 34th St. now].

Robert Murray's, on Jacklam Bergh.

Mr. Wm. McAdam's, and the houses and buildings occupied by Mr. Watson near the old glass house.

Nicholas Stuyvesant's, Peter Stuyvesant's, Mr. Elliott's.

Mr. Horsemanden's commonly called Frog Hall.

Widow Leake's, near Kipp's Bay; for the use of the general hospital of the Americans.

Ordered, That the General Committee of the City of New York do, on application of Dr. John Morgan, Director of Hospitals of the Continental Army, appoint a proper committee of their body, to ascertain and designate to him such houses on Nassau Island, to be by him used as a general hospital, as he may from time to time have occasion for that purpose."

9. AMERICAN ARMY ON LONG ISLAND:

Major General Israel Putnam, Commander; Right Wing, General Lord Stirling—Kichline's Pennsylvania Rifle Battalion, Atlee's Penn. Regt., Smallwood's Maryland Regt., Haylet's Delaware Regt., Huntington's Connecticut Regt.

Left Wing, General Sullivan—Miles' Pennsylvania Rifle Battalion, Bedford Pass; Henshaw's Massachusetts Regt., Johnston's New Jersey Regt., Hand's Pennsylvania Regt.,

Prospect Hill, Wylley's Connecticut Regt.,
Bedford Pass.

Reserve—Little, Hitchcock, Chester.

Two brigades came over after the battle.

Total about 8,000.

Total strength of the American Army August
3rd—Total present and absent, 17,225; sick,
3,678; total effective for duty, 10,514.

10.—BRITISH FORCES AT BATTLE OF LONG ISLAND.

Advance Guard—4 Battalions Light Infantry
and Light Dragoons.

Reserve—4 Battalions Grenadiers, 33 and 42
Foot.

1st Brigade—15, 27, 4, 45 Foot.

2nd Brigade—5, 28, 49, 35 Foot.

3rd Brigade—10, 37, 38, 52 Foot.

4th Brigade—17, 40, 46, 55 Foot.

5th Brigade—22, 43, 54, 63 Foot.

6th Brigade—23, 57, 64, 44 Foot.

7th Brigade—71st, New York Companies, Ar-
tillery.

De Heister, Hessians—Three brigades of three
regiments each; one brigade of two regi-
ments.

Total, forty-three regiments, besides artillery
and small detachments. The total was at
least twenty thousand officers and men—
probably somewhat more than that number.
Some of the regiments were large; the 42nd
numbered 1,168 and the 71st 1,298.

The returns of the British Army on August
27th showed present 26,247 (excluding Roy-
al Americans) and 24,464 effectives.

HQRS. LONG ISLAND, *Aug. 29th.*

11.—Parole Sullivan. Countersign Green.

As the sick are an incumbrance to the Army,
and troops are expected this afternoon from the
Flying Camp in Jersey, under General Mercer,
who is himself arrived, and cover is wanted for the
troops, the commanding officers of regts. are im-
mediately to have such sick removed. They are to
take their arms and accoutrements and be con-
ducted by an officer to the General Hospital, as a
rendezvous, and there to cross together, under the
directions of the person appointed there, taking
general directions from Dr. Morgan. As the above
forces, under General Mercer, are expected this
afternoon, the General proposes to relieve a pro-
portionate number of regiments, and make a change
in the situation of them.

Morgan says that in part of a day and night
several hundred sick and wounded were transported
from Long Island, in a heavy rain which fell dur-
ing the retreat. They were landed at different
wharves and carried to different houses, while he
and his officers had great difficulty in collecting
them in the barracks and hospitals that he had
provided. All possible care was taken, yet some
unavoidably suffered. He gave his personal assist-
ance in dressing the patients, and states that there
was not a single wounded man brought to the
General Hospital in New York (Kings College)
that he did not himself dress. He also assisted in
the operations and visited officers and men outside
the hospital, either alone or in consultation. These

statements give us a better idea of the activities of
a medical director at that time, and more especially
of the energy of Dr. Morgan, who did the work
of superior and subordinate so well that there was
never a complaint of the hospitals where he was
present. The wounded in this case were not in
great numbers, the best estimate being that few
more than fifty seriously wounded escaped from the
affair on Long Island.

The army had scarcely arrived in New York
when the necessity for abandoning the place ap-
peared. On September 5, General Greene urged
that the city be abandoned and burned. On the
seventh a council of war decided on the half mea-
sure that nine thousand men should retire to Harlem
Heights, leaving Putnam with five thousand in
the city. Heath commanded a reserve of two
brigades, and Mercer was in the vicinity of Fort
Lee with the Flying Camp. It was determined to
send the sick to Orangetown, New Jersey, and to
the barracks at Kingsbridge.

Conditions in the city soon became unhealthful.
The letters of Dr. Solomon Drowne, a hospital
mate, to his father picture the rapid change. He
wrote:

June 4th. We arrived yesterday. We waited on Dr.
Morgan today and were kindly received. He mapped
out a course of duty for us at the Hospital, which will
keep us very busy. The College is occupied for the gen-
eral hospital. It is a very elegant building and its situa-
tion is pleasant and salubrious. . . . I have a list of
medicines, purchased here for ye Continental Hospital,
to copy for Dr. Morgan, which obliges me to conclude.

June 17th. As there happened to be some vacancies in
the hospital I have as good a berth as I could have wished
for (the same as Dr. Binney's). We draw twenty dol-
lars a month and two rations per day. . . . We have
been closely employed a good part of ye time, assorting
and putting up medicines for thirty chests.

August 9th. Our wages were raised some time ago (in
consequence of a petition to Congress) to thirty dollars
per month. The pay would be no inducement to stay a
minute in this stinking place, at the expense of health, that
best of blessings. The air of the whole city seems in-
fected. In almost every street there is a horrid smell.

Dr. Morgan had a reserve of stores collected
which, before the evacuation, were sent to Stam-
ford, Connecticut. Had this not been done they
would have been captured. He says:

It being in the most violent heat of summer, and so the
less wanted, I ordered the greater part of the rugs and
blankets, the newest and best beddings, of which I had
collected a very large stock, and a thousand sheets, of
which I had lately got to the amount of nearly two thou-
sand, many of them new, and a number of shirts, at New
York, to be set apart for the purpose, and a large quantity
of heavy hospital furniture, some of the largest bell metal
and iron mortars, a number of crates of vials and jelly
pots, the largest bottles, with the most bulky articles, and
those in the least demand, as some hogsheds and casks
of cascarilla, and other such particulars as we could best
spare, to accompany them. To these I ordered, a share of
whatever we had in so great a plenty, as to not fear being
soon destitute of them: to be added with a small assort-
ment of chosen medicines, to be made up and kept together
in one or two suitable boxes as a reserve.

A vessel was found and these stores set off, under
charge of Dr. Ledyard. They were landed at
Stamford and taken charge of by John Lloyd, Esq.,
in his own house. Later, in fear of a landing by
the enemy, the general ordered them moved some
fifty miles into the country.

A branch of the General Hospital was later

established by Dr. Philip Turner at Norwich, where their stores were doubtless used to advantage. Had they been held in New York they would have been lost, yet Morgan was blamed at the time for sending them away.

The morale of the army at this time was not high. It was composed of a heterogeneous mass of men of all ages, from all the colonies, with a large proportion of militia. The defeat on Long Island was depressing, and on top of that came the news of failure, suffering and death in Canada. The first enthusiasm had waned, and the formidable army assembled by Britain, together with a powerful navy, were things to give pause. Above all, there was now much sickness. During the siege of Boston there had been comparatively little serious disease; now there was a great deal. Dr. Rush says: "It was not until the troops of the eastern, middle, and southern states met at New York and Ticonderoga in 1776, that the typhus became universal and spread with such mortality in the armies of the United States." Rush also says that "the southern troops were more sickly than the northern or eastern troops." This was due to the fact that there was in the south a class of poor whites, not known in New England and the middle colonies. To these may have been due the typhus which ravaged the army. Dysentery was now common in the camps of the Americans and also of their opponents; but usually not of a fatal type. Early in September three additional battalions were ordered up from Virginia, and two from North Carolina. Of those from Virginia (the 4th, 5th and 6th Regts.) nearly one half of the men were sick. A return of the army at the middle of September showed that of the rank and file there were present, fit for duty, 15,243; present sick, 6,098; absent sick, 1,215. The total number of sick was 8,528, more than a third of the army.

Washington was holding on to New York and the sick not yet evacuated. On the 8th of September he asked the New York Convention for four large sloops for this purpose, having no wagons to spare; and on the 12th he wrote again, saying that the vessels had not yet arrived. Dr. Morgan made a considerable tour through western New Jersey in search of a site for the general hospital. On his return he wrote to Washington (September 12th) (12) stating that no suitable place could be found in Orange County, but that Newark was satisfactory, and that the patients could be transported there almost entirely by water carriage; only four miles would be by land transport. Meanwhile, events were compelling action.

On September 9th the British had landed on Blackwell's Island. General Greene again called for a council of war, and this time it was decided that the city must be given up. There was still a large number of sick, more than could be moved in a regular manner. As a necessary measure, Morgan agreed to a plan of Greene's, that the regimental sick of each brigade be collected in a body, placed in charge of a medical officer, and sent off into the country (New Jersey). All not able to move themselves were ordered sent to the general hospital. This measure of necessity produced endless

irregularities and confusion. The sick escaped from all control. Some surgeons also remained away and did not rejoin the army. At the next battle, the White Plains, few regimental surgeons were present, and Morgan was obliged to care for the wounded on the field, as well as at the general hospital at North Castle. The removal of the slightly sick, convalescents, and malingerers left several hundred seriously sick still in the city. Morgan said of the brigade plan: "I am still of the opinion it was the best step that could have been taken to prevent the sick falling into the hands of the enemy, unless, what I mentioned to your Excellency as my wish could have been accomplished, viz.: That protection might be granted to the hospitals on both sides, and the sick not become prisoners of war, but their person and attendants might be privileged and safe, as was the case between the French and English in the wars of Europe." This letter to Washington shows that Morgan understood the principles now embodied in the Geneva Convention. He had served in the last Colonial War and must have been familiar with the practices of the French and English in that war.

On September 15th matters came to a crisis in New York. The British sent war vessels up the Hudson, and at the same time landed at Kipps Bay on the east side of the Island. A brigade of militia ran away, leaving Washington alone and exposed to capture within a hundred yards of the enemy. This is one of the occasions on which he is said to have lost control of his temper. Putnam made his escape to Harlem Heights, in some confusion, with the loss of 275 prisoners, the heavy guns and much supplies. Washington said, "Most of the heavy guns and part of the stores were lost." The loss of stores was due to lack of wagons. He says that the removal of the sick was "completely effected." In a letter to John Augustine Washington he says that they "held on till the sick and wounded were sent away." A more exact statement would be that they got the sick away before they were obliged to leave.

The state of the army after the battle on Long Island was such as to occasion alarm in the mind of John Adams, Chairman of the Board of War and virtual head of such war department as then existed. On September 19th he secured the passage of a resolution requiring daily drills. He said:

This resolution was the effect of my late journey through the Jerseys to Staten Island. I had observed such dissipation and idleness, such confusion and distraction among officers and soldiers, in various parts of the country, as disturbed, grieved and alarmed me. Discipline, discipline, had become my constant topic of discussion. . . . I saw very clearly that the ruin of our cause and country must be the consequence if a thorough reformation and strict discipline could not be secured.

On September 20th he secured the adoption of a set of articles of war, which was practically the same as the articles of the British Army. The British articles were, as he says, a literal translation of the *Articles of War of the Roman Army*.

As before mentioned, Morgan had inspected buildings for a general hospital in Newark. Dr. Foster and Dr. Burnet (13) were placed in charge of this hospital, with seven or eight mates,

and it was prepared for a thousand patients. Part of the medicines and stores at New York were ordered over by the Adjutant General (Reed), and to his personal activity it was due that they were saved. But the valuable part still remained in New York after the British had landed and were supposed to be entering the city. Morgan himself then went back in a boat with some assistants and saved these stores, "like a brand from the burning," as he says. He had previously sent two chests to Kingsbridge for hospital use. His own words give the best description of the evacuation of the sick and wounded from New York.

The sick and wounded above mentioned were landed at Hoebuck and Wehock, &c. Some of our mates fell into the hands of the enemy, and many of the nurses and waiters fled, and the militia ran off and impressed every wagon they could find in the neighborhood.

In another place he describes the actions of the militia:

I have been an eye witness myself to whole battalions running off from Powle's Hook and the Heights of Bergen, upon the firing of a broadside from a man of war . . . although not a man was hurt by that fire. These doughty champions never stopped till they came to Second River, but forced away the very wagons impressed to transport the sick and those wounded at Long Island, to Newark; to carry off themselves and baggage, for many of them chose to ride, to save their legs, in case of being more nearly pursued.

It therefore required some days to get on all the sick and wounded, through many difficulties, from the fright of the inhabitants, and their reluctance to admit of the hospitals being stationed at that place (Newark). I had provisions to collect, a commissary and wardmaster to seek, and nurses and waiters to procure, with everything necessary for the comfortable accommodation of the sick and wounded. I had little enough assistance to perform this task: Your Excellency having enjoined me to leave the most considerable number of surgeons and mates at York Island, in case of need. I made all possible haste, however, to put the hospital at Newark on a safe footing, which I accomplished in about ten days, and then returned to headquarters.

Morgan was even blamed in this affair and feelingly wrote:

All the consequences of the sick suffering for want of necessities—sad spectacles of human woe, presenting themselves in towns, villages and on the roads, and straggling through the country, thereby exciting the terror as well as the compassion of the inhabitants—have been ascribed to my department and the officers under me, at a time when we ourselves suffered and called in vain for assistance from other departments, and, so far as we were able, became fatigue men and laborers to the sick and wounded, as we could procure none from the Army, and, as I mentioned before, many of our attendants and nurses had fled.

This hospital remained at Newark until the advance of the British in November compelled the removal of the sick to Morristown and then to points in Pennsylvania.

On September 19th, Dr. Shippen wrote a rather boastful letter to Congress (from Perth Amboy), informing them that "all the wounded from Long Island were now recovered." These wounded men were never in his charge at any time. He also stated that he had lost but ten or twelve men of twenty or thirty thousand passing through camp. Not half that number could possibly have passed through the Flying Camp. It will be remembered that Dr. Shippen was made medical director of the Flying Camp on July 15th. Al-

though without previous military experience, he soon aspired to a much loftier position and took advantage of his station at or near Philadelphia to ingratiate himself with the members of Congress. He was a born courtier, of good professional ability and high social standing and without fine scruples. While Morgan was in the field, riding on horseback hundreds of miles, gathering supplies from Boston to Baltimore, providing hospitals, instructing incapable surgeons, wrestling with insubordinate officers, and doing surgery with his own hands, Shippen was working on the members of Congress, whose fears were excited by the numerous complaints of conditions which neither Morgan, Shippen, nor anyone else could then have remedied. The bulk of the real complaints came from the Northern Army, where Medical Director Stringer had from the beginning denied and resisted Morgan's authority. Even then Morgan had sent what supplies he could collect and had given what aid was possible. Washington was not approached or consulted in a scheme which was now under way to supplant Morgan. On October 9th Congress passed a resolution (14) dividing the jurisdiction; giving Morgan control of the hospitals east of the Hudson, and Shippen control of those west of that river. This was an indefensible plan, which left no head to the Medical Department, and was sure to bring about confusion and failure. It was most probably a step toward the elimination of Morgan and the placing of Shippen in the supreme position. Meanwhile, Morgan was everywhere, doing everything—except playing politics.

During the absence of Morgan there seems to have been no general hospital with the army at Harlem Heights. On September 18th an order was issued to this effect:

The Regimental Surgeons are to take care of their own sick for the present, until the general hospital can be established on a proper footing. They are to keep as near the regiments as possible, and in case of action, to leave the sick under the care of their mates, and be at hand to assist the wounded.

The headquarters were then at Morrisania. General Greene had command on the Jersey side. Sickness continued and even increased. The sick filled houses, barns, outbuildings; they even lay under trees and in fence corners. Washington was not unmindful of them, and on September 16th—an eventful day—a letter was written asking that the pay of nurses be increased (15). He also asked Congress for camp kettles, tents, blankets, and other necessities, to replace those lost during the retreat from New York. Several hundred carts and wagons had been sent to Long Island in July; when the retreat took place they were lost. So when the army retired from the city there were few wagons for baggage, and the camp equipage of tents and other essentials of Putnam's regiments were left behind.

Washington wrote Congress again, on September 24th, concerning the surgeons as follows:

No less attention should be paid to the choice of surgeons than to other officers of the army. They should undergo a regular examination, and if not appointed by the director general and surgeons of the hospital, they ought to be subordinate to and governed by his directions.

The regimental surgeons I am speaking of, many of

whom are very great rascals, countenancing the men in sham complaints to exempt them from duty, and often receiving bribes to certify indispositions with a view to secure discharges or furloughs.

But independent of these practices, while they (the regimental surgeons) are considered as unconnected with the general hospital, there will be nothing but continual complaints of each other—the director of the hospital charging them with enormity in their drafts for the sick; and they him for denying such things as are necessary. In short, there is a constant bickering among them, which tends greatly to the injury of the sick, and will always subsist till the regimental surgeons are made to look up to the director general of the hospital as a superior. Whether this is the case in regular armies or not, I cannot undertake to say; but certain I am, there is a necessity for it in this, or the sick will suffer. The regimental surgeons are aiming, I am persuaded, to break up the general hospital, and have in numberless instances drawn for medicines, stores, etc., in the most profuse and extravagant manner for private purposes.

Washington was not deceived in any of these things; his observations were remarkably accurate.

A considerable number of barracks and huts were built at Harlem Heights and Kingsbridge. The men were crowded in these, and the sick increased. Dysentery and typhus were the principal affections. Little mention is made of smallpox. As a rule, the men in the army about New York had by this time had smallpox, either in the natural way or by inoculation. Surgeon James Tilton of the Delaware regiment afterwards wrote of the sickness which he saw at this time:

In the year 1776, when the Army was encamped at King's Bridge in the State of New York, our raw and undisciplined condition at that time, subjected the soldiers to great irregularity. Besides a great loss and want of clothing, the camp became excessively filthy. All manner of excrementitious matter was scattered indiscriminately throughout the camp, insomuch that you were offended by a disagreeable smell, almost everywhere without the lines. A putrid diarrhoea was the consequence. The camp disease, as it was called, became proverbial. Many died, melting as it were, and running off at the bowels. Medicine answered little or no purpose. A billet in the country was only to be relied on. When the enemy moved to the East River, our army moved to White Plains and left their infectious camp and the attendant diseases behind them. It was remarkable, during this disorderly campaign, before our officers and men could be reduced to strict discipline and order, the army was always more healthy when in motion, than in fixed camps.

I recollect in the campaign of '76, while our army was on the peninsula of New York, we were so deranged as to be deprived of ovens, and flour was served to the troops instead of bread. We could only make sodden bread and dumplings. Some baked their bread on hot stones, and others in the ashes. The consequence was that many were afflicted with the jaundice. Being a regimental surgeon at that time, I shared the fate of the rest, and shall never forget my fatiguing march from the North River to Brunswick, with the jaundice on me.

A return of the army under Washington on the east side of the river, of September 30th, shows that of the rank and file there were: Present, fit for duty 15,104; present sick, 4,211; absent sick, 3,399; total sick, 7,610.

General Greene had at Fort Washington and on the west side of the river 3,531 present fit for duty; 964 present sick; and 259 absent sick. A considerable part of both forces was made up of the militia, which was poorly equipped and had little or no tentage. An order of September 30th directed the militia to "build huts with straw, rails, and sod, on the Morrisania side of the Harlem." An order of the 28th directed that the boards sent up for

tent floors be not used for building up walls. On October 4th an order was issued bearing on the situation of the camp.

Orders:—The shameful inattention, in some camps, to decency and cleanliness, in providing necessaries, and picking up the offal and filth of the camp, have been taken notice of before in general: after this time particular regiments will be pointed out by name when such practice prevails.

At this time an engagement was generally expected. General Heath issued an order of battle for his division on October 3rd, in which provision was made for attention to the wounded. "A stout, able-bodied man of a (each) company is to be appointed, who, with the camp colourmen and musick, are to assist the wounded."

The British having landed at Throg's Neck, the Continental Army was drawn back to the line of White Plains, early in October. It was now organized in four divisions under Lee, Heath, Sullivan and Lincoln. Greene was allowed to leave twenty-seven hundred men in Fort Washington. This was contrary to the judgment of Washington. For once, as Reed intimates; the decision of the great man faltered, and the foundation was laid for adding another to the growing list of disasters.

When Morgan returned from Newark to headquarters he received a letter from one of the aides-de-camp "setting forth the miserable situation to which the sick were reduced, and the clamor for want of medicines, absolutely insisting on immediate and sufficient supply," and saying that, "whilst he was reserving the medicines for cases of emergency, the sick were dying in numbers, for want of a necessary supply." Morgan had just sent to Mr. William Smith, the continental druggist at Philadelphia, with what success may be judged. "Instead of ten pounds of tartar emetic I sent for, four ounces were all I could obtain." He then induced a regimental surgeon to go at once to Hartford, Norwich, Providence and Boston, to procure medicines; but these places were so very bare of them that he was greatly disappointed in the outcome. He next applied to Governor Trumbull of Connecticut, and in person to the Assembly of New York at Fishkill. He found that the stock owned by this state had been sent to the Northern Army. Governor Trumbull collected a supply for him, but it did not reach the army until November.

This was an incident in his labors. As has been stated, the general hospital with the army suffered while he was away; rather, it ceased to exist. It was necessary to establish it again. As the army was then looking toward New Jersey, he decided to establish a hospital at Hackensack. He says:

I recommended Hackensack. Every general officer, to whom it was mentioned, approved of it, as the most suitable place of all others for the sick of the army on York Island, there being no such convenient place on the Island itself, and the enemy had just made a descent about Kingsbridge. I was ordered over the river to view Hackensack (probably about October 1st) and to report what number of sick could be provided for at that place. On my return I did accordingly report that if a sufficient number of carpenters and masons were set to work immediately, to fit up the church, manufactory, and a storehouse or two, &c., six or seven hundred men, and perhaps more, might be accommodated in the town and neighborhood; but it would require many workmen and some time to prepare places for their convenient reception. I was

then ordered back to carry the plan into execution with all possible diligence. I went accordingly, and next day no less than three hundred men (sick) were brought into the neighborhood for me to look after, though I was quite alone in respect to help. They daily increased in numbers, so that within a few days they amounted to upwards of a thousand (16). I had left instructions for Dr. Warren, and a number of mates and other hospital officers to follow and attend the sick. At first we had neither bread, flour, nor fresh provisions in readiness, nor were Commissaries at hand, from whom I could obtain any help. General Greene, to whom I sent to Fort Lee for assistance, was gone over to York Island. So soon as my hands were strengthened with Dr. Warren's and Mr. Zabriskey's help, and the appointment of a commissary and quartermaster, difficulties abated by degrees, and our affairs got into a more promising train. In the meantime, the armies having reached toward the White Plains, a battle was expected. I therefore hastened to join your Excellency. (This seems to have been about October 25th.)

The British had slowly moved forward, and toward the end of October were ready to attack. Morgan found that the surgeons with the army had fixed upon the church at North Castle as a convenient place for the wounded and at a suitable distance from the expected conflict at the White Plains. He set about preparing the place, but before it could be done the battle began. As mentioned before, many of the regimental surgeons were absent, having gone off with their sick and not returned. Morgan learned of this and went at once to the field to supply this deficiency. He says:

While we were getting in readiness, a firing of cannon was heard anew, for there had been a firing heard the day before at Fort Washington. On learning it was at the White Plains, every surgeon of the hospital then present set out with me, immediately for the Plains, several mates following with a waggon, to bring the instruments and dressings. We fixed (located) near the lines, and I never stirred from thence till the enemy retreated, which was about a week later; nor till Your Excellency crossed the river to hasten to the support of Fort Washington (about Nov. 12th). In the meantime the situation of affairs would not permit Your Excellency to give me leave to return to North Castle, but for a few hours, to give directions, and to assist in providing for the sick and wounded; one hospital surgeon, and sometimes two or more, with three or four mates, attending the whole time at the Plains, in expectation of a second attack.

(To be concluded)

LONDON LETTER.

(From our own correspondent)

Medical Education in Great Britain.

LONDON, August 27, 1920.

The question of medical education is of intense interest to medical men in all parts of the world. It is in a state of flux in Great Britain, or, more correctly, it is in a state of transition. It is believed that too much attention is paid nowadays to bacteriology to the neglect of clinical medicine. The argument is made that it is the clinical experience which counts, for if one cannot make a correct diagnosis without always resorting to the services of the laboratory man, then the practice of medicine is in a parlous condition. It must be remembered that the largest proportion of medical practice is in the hands of the general practitioner, who has to rely on his own trained powers of diagnosis and in the vast majority of cases must dispense with the aid of the laboratory. The time may come, and it will

come if the Consultative Council of the Ministry of Health has its way in England, when the general practitioner will have at hand facilities for laboratory aid. This does not mean, of course, that the student should not be thoroughly trained in clinical methods of diagnosis. The laboratory should be the coadjutor to clinical methods and must not be allowed to dominate the situation.

It is painfully evident that in this country, and probably also in all civilized countries, the medical curriculum is far too comprehensive. Sir George Newman, chief medical adviser to the British Ministry of Health, in an excellent review of the state of medical education in England, which he presented at the recent meeting of the British Medical Association, emphasized these points. He declared that the medical curriculum required lightening at both ends and that the question of lightening without lengthening the curriculum was one of cardinal importance. He suggested several ways to accomplish this object and ended by stating that in his opinion there was need of further state aid, but with a minimum of state control. He pointed out that the cost of proper medical training has now risen beyond the means of the average man, and yet it was in the interest of the state to secure well equipped doctors. To provide a satisfactory medical education more teachers were needed, better teachers and better paid teachers. Clinical units were needed. Improved laboratory accommodation and better equipment were needed. An extension of hospital and clinical facilities were needed. All these called for money and organization which had been lacking in the past. As Sir George Newman truly said, the education of the medical man was no longer a matter of proprietary or professional interest, it was of national concern, for the health of the people was the principal asset of the state. Other well known authorities on medical education aired their views and it is obvious that while on some points they did not agree, they were unanimous in believing that there should be changes introduced into the methods of British medical education.

In the Student's Number of the *Lancet* an exhaustive account is given of medical education in Great Britain and it will not be out of place to quote some of the statements with regard to the powers, duties, and constitution of the General Council of Medical Education and Registration of the United Kingdom. It is first a registering body; no person, even though he has the proper qualifications, is a legally qualified medical practitioner unless his name appears on the medical register. Secondly, it is a standardizing body, insuring the keeping of medical education up to efficient standard by scientific examinations. Thirdly, it is a plenary and disciplinary body, having power to remove from the register any practitioner adjudged guilty of conduct "infamous in a professional respect." Fourthly, to the council is committed the codification of pharmaceutical remedies. The council at present consists of thirty-eight members, of whom all but eleven are official representatives of some corporate body. Five members are chosen by the Crown on the advice of the Privy Council and six others are elected by the members of the medical profession as direct representatives.

The educational curriculum is as follows: The course of professional study after registration occupies at least five years. The final examination in medicine, surgery and midwifery must not be passed before the close of the fifth academic year of medical study. The following are the General Medical Council's regulations in reference to the registration of students in medicine. Every medical student should be registered in the manner prescribed by the council, and the registration of medical students is placed under the charge of branch registrars. Every person desirous of being registered as a medical student should apply to the branch registrar of the division of the United Kingdom in which he is residing and should produce or forward to the branch registrar a certificate of his having passed a preliminary examination as required by the General Medical Council and evidence that he has attained the age of sixteen years, and has commenced medical study at an institution approved by the council. The branch registrar shall enter the applicant's name and other particulars in the students' register and shall give him a certificate of such registration. The commencement of the course of professional study recognized by any of the qualifying bodies should not be reckoned as dating earlier than fifteen days before the date of registration. In addition to the universities and schools of medicine, there are many institutions where medical study may be commenced.

The one change in the development of medical education which has taken place recently in some of the British medical schools is the establishment of clinical units. Sir George Newman referred to this matter in the address quoted previously and, while protesting that there was nothing celestial about the clinical unit, said that it was merely a matter of convenient arrangement by which three general advantages were secured. 1. The clinical teacher devotes a regular and substantial proportion of his time to his teaching work and instead of being casual, secondary, incidental or spasmodic, it becomes his chief task, and for the student instruction in clinical medicine and surgery is thus systematized, thorough and always available. 2. The unit consists of a staff of competent men working as a group or team who pool their experience—the physician, the assistant physician, the resident physician, the house physician, wards, outpatient department, laboratory, auxiliary departments for special forms of treatment, all in a composite unit. 3. There is full integration of the science and art of medicine and surgery, the teaching of which may thus be raised to university standards. There is the association of research with study, and the study itself is intimate and intensive. It should comprehend Sir James Mackenzie's subjective and associated phenomena, it should investigate the mechanism of symptoms, and it should follow end results back to their origin. The example on the largest scale in Great Britain is at Edinburgh, where there are seven surgeons in the unit; Sir Harold Stiles is regius professor of clinical surgery, with an assistant surgeon, a clinical tutor, and a house surgeon. The unit contains forty-four beds, outpatients and laboratory accommodations adjoining.

The work of the week comprises ward clinics, systematic clinical lectures, tutorial classes and operations. There is intensive study of the cases and exceptionally full integration of anatomy and pathology with surgery.

In the Student's Number of the *Lancet* a leading article is devoted to medical training and the clinical units and a lucid explanation is given as to why such a development was called for. It is pointed out that the time was when the whole of medical education was in the hands of the working leaders of the profession and progress was great in those simpler days. But as learning became more intense, as well as of a greater range, the preliminary and intermediate subjects passed into the hands of teachers with special equipment, the instruction in the principles of medicine and surgery being left to the honorary staffs of the voluntary hospitals. These men earned their living by private practice, carried on during time that was already heavily pledged to gratuitous labor in the wards. Scientific research and systematic teaching of the students were prosecuted in addition to their duties to private and hospital patients and with results of which all may be proud. But the strain was obviously too great, while in election to the honorary staff capacity or inclination for teaching carried but little weight. Nor was the appointment of the clinical teachers under the control of the medical school attached to the hospital, so that every teacher was a law unto himself, and the whole organization was at the mercy of the less conscientious members of the staff. That these were few proves the rectitude and enthusiasm of a large number of men, but for some time it has been known that a more efficacious and orderly scheme, one less dependent upon personal sacrifice, must be found to supplement the clinical education of the student. The scheme is designed to correct defects that have arisen in the system as science has progressed.

It may be mentioned that the idea of clinical units was suggested by the late Sir William Osler and Mr. Abraham Flexner. It is likewise worthy of notice that in each of the five schools which have established clinical units special room and laboratories have been allocated or are to be constructed for research, and the assistant directors, as well as the directors, will have opportunities for investigating patients under their own charge as inpatients. In every case it is proposed eventually to institute research studentships, so that promising juniors may be trained after qualification in the methods of research. The arrangements for research will vary with the individual bias of the investigators and moreover, will have no direct connection with the undergraduate, except in so far as he is being taught by men who are keenly alive to the importance of discovering a scientific basis for medical practice. It would appear that for all concerned the institution of clinical units signifies the simplification of medical training, as well as tending to great thoroughness and general efficiency. It is well to know that medical education here is not at a standstill or marking time, but is striding forward in keeping with the trend of modern medicine and surgery.

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL

INCORPORATING THE

Philadelphia Medical Journal
and the Medical News

A Weekly Review of Medicine.

Address all communications to
A. R. ELLIOTT PUBLISHING COMPANY,
Publishers, 66 West Broadway, New York.

Subscription Price: Under Domestic Postage, \$6; Foreign
Postage, \$8; Single copies, fifty cents.

Remittances should be made by New York Exchange, post office
or express money order, payable to A. R. Elliott Publishing Co.,
or by registered mail, as the publishers are not responsible for
money sent by unregistered mail.

Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, SATURDAY, SEPTEMBER 25, 1920.

THE THERAPEUTIC IMPORTANCE OF PSYCHOLOGY.

The importance of psychology as a science and its value in medicine is more and more in evidence as time goes on. It is not so long ago that the views of Freud, who taught that the unconscious mind is released into activity from the shackles that the conscious mind puts into it only during sleep, were condemned and despised. Although the teachings of the Viennese professor are not accepted by all, the basic principles of his theory are now generally agreed to. This was shown at the meeting of the British Association for the Advancement of Science held recently in Cardiff, Wales, where in the section devoted to psychology five papers out of every six read revealed the influence of Freud.

Another branch of psychology which is rapidly coming to the fore is that of industrial psychology. However, to return to the matter of investigating the unconscious, it may be said that an excellent paper was read at Cardiff by Dr. C. W. Kimmins dealing with the dreams of children who are physically abnormal. The speaker pointed out that the great value of the dream of the neurotic in the diagnosis of cases of mental disturbances had been proved beyond all dispute in the treatment of war neurosis and a great variety of nervous ailments. On the other hand, the dream of the normal healthy child also appeared to him to open up a very useful field for research as being the best method of investigating the unconscious which played such an important part in human behavior.

At the title denoted, the paper by Kimmins was taken up with the investigation of the dreams of physically abnormal children. Dealing with an investigation of the dreams of five hundred physically defective children, blind and deaf but not suffering from mental defects, he said that the dreams of the physically defective differed from those of the normal in the following way: 1. First, they dream far less about food, from which it would appear that the crippled child is better fed than the normal child. 2. Among the fears, a larger proportion dream of accidents, and the fear of animals is clearly greater than among normal children. 3. The kinesthetic or falling dreams are more common, especially at the ages of thirteen and fourteen years. 4. Among the fulfilled wishes, visits to the country bulk very largely. 5. The death element in the dream occurs more frequently than is the case in normal children, and more even than in the dreams of the deaf and blind.

Kimmins analyzed and discussed the subject at length and concluded that from an educational point of view there was in the dream a valuable and fascinating field for research and that a further study of the dreams of children who were physically abnormal might clear the way to a fuller understanding of the significance of the dreams of normal children. A careful study of children's dreams might throw much light on the study interests and desires of the child at different ages and especially where persistent dreams were recorded of unfulfilled wishes or those elements which were conspicuously lacking in the life of the child, and which might seriously interfere with his natural development. From various sources there comes a mass of evidence as to the great influence the unconscious exerts in every department of mental activity, and a fuller knowledge of the unconscious might be as essential in dealing with the normal development of children as in the abnormal cases in which it has proved to be of such extraordinary value.

The veteran anthropologist, Karl Pearson, at the same meeting also paid his respects to psychology, saying that a good knowledge and practice of the science were of the utmost use in all phases of human endeavor and especially so to the State and to industry. He even went so far as to affirm his belief that the war might possibly have been prevented and certainly many of its horrors assuaged if properly directed psychology had been allowed free sway. That psychology is of great therapeutic value in the diagnosis and treatment of certain complaints is now a matter of common knowledge.

PHYSICIAN-AUTHORS—GEORGES B. E. CLEMENCEAU.

Everybody, of course, knows Georges Benjamin Eugene Clemenceau, France's Grand Old Man, for his fame was so recently at its high tide. Destiny cast him for an heroic rôle on the grand stage of life, the rôle of statesman at an hour when his country needed all the genius of statecraft he could bring to bear on the situation. It is in that rôle that we know him, but he has played other rôles in his time and played them well. The chief of these minor activities were as a physician and as a writer. He became a physician through the influences of heredity and parental suggestion; for three hundred years without a break his forbears had been physicians; and he became an author through a temporary eclipse of his political fortunes.

Clemenceau's career as a physician was brief, but notable and unique. Doubtless the troubled political conditions in France at the time served to cut it short. He was a republican, and the Second Empire was at the height of its fame and influence when he studied medicine in Paris. His father had been a leader of radical republicans in the picturesque Biscayan village of Mouilleron-en-Pareds, where Clemenceau was born (in 1841), and imparted to the son those strong democratic tendencies which have been the outstanding characteristic of his political career. Naturally, then, he was a bitter foe of the Empire. Before he was twenty-five years old he was imprisoned for shouting *Vive la République!* at an Imperial celebration. He served his term and then, practically in exile, came to New York. This was in 1866, within a year after he had received his medical degree. As a student he had shown marked medical aptitude and his thesis, *The Generation of Anatomical Elements*, written at his graduation, was acclaimed the ablest paper published by the Faculty of Medicine that year. This gave him great advantages, but he ignored them and established himself in the Montmartre section, where he began treating patients gratuitously and expounding republican doctrines to them. It was from this practice that he was driven by the semivoluntary exile.

In New York Clemenceau tried to build up a practice but failed, and so went to Stamford, Conn., where he taught French in a girls' school. It was in America he did his first writing, letters to *Le Temps* of Paris on social and political conditions here, and at Stamford he translated John Stuart Mill into French. Early in 1870 he returned to Paris and resumed his Montmartre practice. Then came the disastrous Franco-Prussian war and the collapse of the Second Empire. His dream had

been realized and destiny had launched him fairly on his political career. In a short time he was weaned wholly away from medicine, coupling journalism with politics to increase his power. He had a ready pen and a bitter one, and it was at this period that his ability to upset cabinets earned him the name of the Tiger. In 1880 he founded and edited *La Justice*, a daily, and wrote about anything and everything, but mainly about politics. This periodical was suspended three years later when Clemenceau fell from political eminence with astonishing suddenness, due to charges in connection with the Panama Canal scandal. Although he met every charge, his constituency turned solidly against him and for nine years he had no connection with the government of France. Immediately he became a man of letters and during the nine years wrote one novel, two volumes of tales and sketches, a volume of sociology, a play with scenes laid at the court of China, a quantity of ordinary journalism including articles on the Dreyfus case which make four fat volumes, and several other books. His best known work is the volume of essays, *Great Pan*, which critics assure us is replete with ironic grace and humor and a delicate classical spirit. Episodes that grew out of his experience as a physician are contained in the two volumes of tales, and these are said to be his best fiction, grimly picturesque, clear cut and full of realism. His novel, *The Strongest*, a severe criticism of social life, was a dull and tedious failure. Recently it was published in translation in America, not because of its merit but because of widespread interest in the author.

When the Dreyfus case developed Clemenceau founded *L'Aurore*, devoted to proving Dreyfus innocent. It was in *L'Aurore* that Zola published his famous *J'Accuse*. No less a critic than Sidney Brooks has said that Clemenceau's Dreyfus articles are "the most brilliant masterpieces of polemics that French literature has produced since Pascal's familiar *Provincial Letters*." It was these articles that restored him to that political power which culminated in the premiership.

What may perhaps be Clemenceau's last volume is a book entitled *France Facing Germany*, a collection of speeches and articles on the origin of the World War and the progress of hostilities—a volume that doubtless will be of great historical value in future years. In style Clemenceau's writings are fluent and vivid always, an admirable byproduct that serve to show the almost limitless capacities of a very remarkable man.

At present, Clemenceau is again somewhat in eclipse because of dissatisfaction with the peace-making and nearly all French newspapers are re-

viling him and accusing him either of incompetence or treachery. Only a few months ago he came near being President of France. Several journals have urged him to take up the pen again in his defense, but the old statesman has declined and his decision appears irrevocable. He is seventy-nine and his fame is secure. He can afford to regard it all as a sardonic joke.

ERYSIPELAS IN ELDERLY SUBJECTS.

Of all the local complications of erysipelas in elderly people suppuration is the most frequent, arising in the phlyctenæ—rare in old subjects—or in the cellular tissue underlying the dermatitis, preferably where it is loose. They are due to the streptococcus alone and not to an association with the staphylococcus. Suppurating erysipelas is also observed, while gangrene of the limbs and scrotum has been met with, especially in cachectic, diabetic, and renal subjects. An acute angina at the onset of erysipelas, suppurating otitis media, and lesions of the ocular and nasal mucosa are very common. In thirty cases of erysipelas in old people, Lamy met with a mild catarrhal conjunctivitis and once a conjunctivitis with dacryocystitis; both were bilateral. The streptococcus was found in pure culture, but the conjunctiva and ocular globe did not become involved.

The most frequent local complication, according to Lamy, is sclerosis of the derma of the face, a sequela of the streptococcal dermatitis. The thickening of the derma is accompanied by redness over the site of the erysipelas that has disappeared and may lead one to suspect a return of the process, but the absence of local hyperthermia is the best sign that such is not the case. This hard edema is more frequent in the lower limbs and face and is more prone to occur in relapsing erysipelas. Bendix, Dupouy, and others have shown that in the face the lesion is a pachydermic change without any inflammatory process, and in the area of the sclerous dermatitis the lymph does not contain the streptococcus.

In Lamy's cases this special type of scleroderma was accompanied by a cutaneous vasodilatation which gave rise to the redness of the skin. The frequency of infectious erythemata during and following the various infectious processes are well known, this frequency being due to the very marked action of the microbic toxins on the vasomotor centres. The toxins stimulate the vasodilators so that they react with the greatest facility and the redness remaining after erysipelas is a manifestation of this action. These vasomotor disturbances may awaken a latent eczema or cause an outburst of syphilides in old syphilitics.

The general complications during erysipelas in the aged are regarded as common by most observers, and death is frequent, although it is due not to a streptococcal infection but rather to the insufficiency of some viscus. The early or initial pulmonary congestion often observed should be looked upon as a symptom of erysipelas and not as a complication. Enriquez and others believe that renal complications are frequent in erysipelas in old people but Lamy never met with any.

Besides the true visceral complications, visceral disturbances with a favorable prognosis are also met with, according to Lucien and Parisot. According to these observers renal, hepatic and cardiac complications arise in organs previously the seat of lesions. Streptococcal endocarditis, pericarditis and pleural empyema have been observed as complications of erysipelas in the aged. Pneumonia and pulmonary congestion have also been described. The pneumonia of erysipelas has a rapid evolution, a vague symptomatology, and a fatal issue, and to detect it at its onset the thorax should be given a daily auscultation, otherwise the lung process may not be recognized.

Delirium is a common complication of all infectious processes in elderly people and often afterward the first symptoms of senile dementia arise.

Of the abnormal types of erysipelas in the aged may be mentioned the bilious and adynamic forms, although they are uncommon. Recurring erysipelas is far more fatal in elderly subjects than in adults because their systems are less resistant. A progressive attenuation of the specific dermatitis may be observed in them and each recurrence reveals a growing opposition between general immunity and the local predisposition, both increasing after the previous attack.

SPIRITS AND SCIENCE.

Suppose a violent shaking of the earth amid an accustomed peaceful scene. In its train will be found cast up fossils, relics of a time so long forgotten that these objects appear to the inhabitants of the green earth utterly strange and new. They do not belong to the familiar soil. Their origin must have been some unknown land from which they have intruded upon the view. Such an earthquake, in greater or smaller proportions, occurs at every crisis in individual life or in that of nations. At such time intruders seem to make themselves felt, apparently unfamiliar and so attributable to almost any external agency. Is it strange that in the psychic upheavals of the past six years there has been a strong revival of belief in such presences,

intruding in daily affairs or more softly coming to visit their own living ones?

One of the world's keenest modern psychologists explains on the basis of such cataclysmic disturbances this present day revival of the really never extinct belief in spirits. In a timely address before the Society for Psychical Research in England, Jung¹ presents scientific facts to explain that inner psychic experiences give origin to such belief in spirits. He does not deny "that mystic and supernatural something which alone makes a man a man." He shows how man could create this, however, out of his own buried psychic life. Thus man preserves something about himself which has ever recurred in one form or another to preserve him from a demoralizing materialism. Man's perception of the natural world around him, as well as of his inner psychic activity, has always remained the same. His interpretation of it has varied with time and with change in intellectual viewpoint. Particularly in more primitive times man has been more prone to interpret the things he perceived arising from his inner psychic realm as ghosts coming to him from without. Later he has weakened this conception by calling them merely dreams or morbid symptoms, without even consideration enough for them to stop to inquire their significance. They were still foreign to his external thought, which he was inclined to think was all there was of his mental activity. Yet under special stress they might take on for him the appearance of objective reality.

Now, however, science has laid its hand on the dream, the apparition, the neurotic imagining. Each one yields itself as a product of the mental life but lying so deep, sometimes so separated from the ego's realization of itself that when it appears it has the force of a foreign intruder. Jung likes to describe the unconscious as separated into two parts. He names first an individual unconscious made up of experiences which have been repressed below consciousness within the individual's own life. These are not felt as foreign to the ego when they are again brought into its ken, as through the process of analysis. But there is also a larger unconscious, which he calls a superpersonal or collective unconscious, meaning thereby the "congenital instincts and primordial forms of apprehension" which belong not to individual experience but which appertain to the whole of mankind. These appear to consciousness as foreign, adverse. Traces of such archaic images appear in dreams and in more disturbing form in certain cases of mental derangement, chiefly in dementia præcox.

There are, and always have been, people of more than the usual range of intuitive perception. They have been able to grasp more than others of this larger unconscious and translate it over into new ideas. These may be acceptable, answering perhaps to an unconscious preparation which has tended toward their acceptance. They may prove unacceptable and conflict too violently with what has long been held true. In either case there occurs a change in conscious thought and in consequent activity, which on such grounds needs no explanation of extrahuman intervention but has its origin only in the larger human life of the past as well as of the present. The appearance of departed spirits rests upon the same psychic mechanism. Furthermore, the amount of psychic energy attached to a loved one is applied, when the object is removed by death, to the mere image or idea of that object. This attachment of energy to an image may so separate this portion of psychic energy from the personal ego that the image attains the force of a separate existence. The loss of this energy may even be felt to such an extent that the spirit itself is accounted an injurious presence.

Jung makes no arrogant assertions which deny the possible independent existence of actual spirits. His familiarity, however, with the content and the mechanisms of the unconscious gives weight to this scientific basis for the spiritual phenomena which have always been present in man's speculation. It should help to steady intellectual thought in these days when spirits of many sorts have been roused from their psychic hiding places.

NEEDLESSLY BLIND.

The days when workmen were seriously injured and incapacitated for work through no fault of their own are rapidly coming to an end. Formerly a small compensation or tiny pension calmed the employer's conscience; now the law is standing outside the door and none may keep her from the discussion of how much shall be paid. The employer's one loophole is contributory negligence, and this happens very frequently, for, to the employee, it seems waste of time to take precautions against an evil he has never had to face and which, to his knowledge, has never happened where he works. So the National Committee for the Prevention of Blindness has to state that out of the one hundred thousand blind in the United States more than fifty per cent. are needlessly so. The national council estimates there are two hundred thousand eye injuries in our land and the International Association of Labor Legislation has issued a list of fifty-six industrial poisons of which thirty-six affect the eyes. Men repeatedly disobey the foreman and neglect to wear the goggles provided. They complain they are heavy, disagreeable to wear, and some-

¹ C. C. Jung, *The Psychological Foundation of Belief in Spirits*, Proceedings of the Society for Psychical Research. Part LXXXIX, Vol. XXXI.

times become cloudy. The providing of individual goggles, insistence on their being worn, removal of dangerous vapors and gases and properly ventilated and lighted rooms, ought to remove all objections, but many times when the employer is honestly doing his best, the employees behave like children. Practically all California's eye injuries are caused by flying objects, small pieces of steel or emery dust. The injured one's plea was that he only had to do one minute's grinding at the emery wheel and did not wear goggles as he thought nothing could happen in that time. Stodgy ignorance, willful or pardonable, is one of the slowest but most vicious devils the medical profession has to encounter.

News Items.

Smallpox in Scotland.—To date 474 cases of smallpox have been reported in the Glasgow district. Vaccination is stated to be falling off.

New Philadelphia Hospital.—A new hospital to be known as the Robert H. Crozer Hospital will be erected on the grounds of the Chester Hospital, Philadelphia, and deeded to that institution for ninety-nine years.

State Institution Leased by Government.—The United States Government has leased the former state home for inebriates at Knoxville, Iowa, and will remodel it as a hospital for former service men in the Middle West.

Course in Sex Education.—Announcement has been made by the University of Cincinnati of a new course dealing with sex education. The subject will be presented from the sociological and psychological as well as the biological viewpoint.

Walter Reed Hospital Work Filmed.—A film showing the work at the Walter Reed Hospital, Washington, for wounded soldiers, from a physical, educational and recreational viewpoint, will soon be exhibited through the efforts of the Potomac division of the American Red Cross Society.

Neurological Society Meets.—A stated meeting of the New York Neurological Society will be held on October 5th. Papers will be presented by Dr. Junius W. Stephenson on Clinical Studies of Syphilis of the Central Nervous System and by Hannah M. Creasey on Stuttering: Etiology and Therapy.

Proposed Memorial to Major General Gorgas.—An international institute for the study of tropical diseases, to be established in Panama, has been proposed as a memorial to the late Major General William C. Gorgas. It has been stated that the government of Panama is willing to donate the St. Thomas hospital for the use of the institute.

Akron's Twins.—Akron, Ohio, is having an epidemic of twins, according to a press dispatch quoting figures at the Bureau of Vital Statistics. Akron lays claim to the largest proportion of twins to other births of any city in the union. In 1919 forty-six pairs of twins were born, and forty-one pairs have already been born up to August 31st of this year. Of the 1920 twins, sixteen pairs are male, twelve female, and thirteen mixed.

Safety Congress.—The ninth annual safety congress of the National Safety Council will be held September 27th to October 1st in Milwaukee.

Red Cross Magazine Discontinued.—The *Red Cross Magazine* will suspend publication with the October issue, on account of the increased cost of paper and publication.

University of Sydney.—Dr. J. T. Wilson has been elected dean of the medical faculty of the University of Sydney, Australia, succeeding the late Sir Thomas Anderson Stuart.

Battleship Laboratories.—The British Ministry of Agriculture is arranging to employ obsolete battleships as floating laboratories for the investigation of foot and mouth disease.

Chair of Pharmacology.—The University of Sheffield, England, has established a whole time chair of pharmacology to which Dr. Edward Mellanby, at present professor of physiology in the University of London, has been appointed.

Increase in German Women Students.—Reports from Germany state that there are at present approximately 8,000 women studying in German universities, twice the number registered five years ago. Of these, more than 2,000 are medical students.

Queen's Medical College.—Dr. Lorimer J. Austin, of London, has been appointed professor of clinical surgery and Dr. James Miller, of the University of Edinburgh, has been appointed professor of pathology in Queen's Medical College, Kingston, Ont.

French Orthopedic Congress.—The second French Orthopedic Congress, will be held October 8th and 9th in Paris. The questions to be considered are: Treatment of scoliosis by Abbott's method; ischemic retraction of Volkmann; treatment of paralysis by tendinous anastomosis.

Redard Prize.—A fund yielding an income which is to be awarded as a 5,000 franc prize every fifth year for the best work on orthopedic surgery, has been bequeathed to the Académie de médecine, by Dr. P. Redard, a prominent French orthopedic surgeon. Physicians of all countries and interns in Paris hospitals may compete.

Meeting of Colored Physicians.—The National Medical Association of Negro Physicians, Surgeons, Dentists and Pharmacists held its annual meeting August 25th to 27th in Atlanta, Ga., under the presidency of John P. Turner, of Atlanta. Dr. Henry M. Green, of Knoxville, Tenn., was elected president and Louisville, Ky., was selected as the next place of meeting.

Classification of Paris Professors.—Professors in the Paris Faculty of Medicine are said to have been placed in two categories according to their seniority, receiving, respectively, twenty-five and and twenty-three thousand francs yearly. Professors Richet, Pouchet, Hutinel, De Lapersonne, Gilbert, Roger, Nicolas Ribemont-Dessaignes, Quénu, Prénant, Widal, Chauffard, and Weiss have been put in the first class, and Professors Delbet, Marfan, Hartmann, Bar, Marie, Broca, Teissier, Desgrés, Lejars, Achard, Robin Legueu, Letulle, Couvelaire, Carnot, Besançon, Vaquez, Dupré and Jeanselme in the second class.

Sixth International Surgical Congress.—It has been decided by the recent Paris conference that the sixth congress of the International Surgical Association will be held in London in 1923, under the presidency of Professor MacEwen, of Glasgow.

Funds for Broad Street Hospital.—In view of the splendid work done by the Broad Street Hospital, New York, during the Wall Street explosion of September 16th, a movement is under way in the financial district to solicit funds for this institution. It was revealed that the quarters and staff of the hospital are too small for such emergencies.

Immigrants to Be Vaccinated.—Orders for the vaccination of all third class passengers leaving European ports for this country have been issued to United States Public Health Service surgeons in Europe by Dr. Rupert Blue, formerly surgeon general of the Service. The precaution has been taken to prevent the spread of smallpox from Central Europe. Dr. Blue has also announced that more health officers are soon to be sent abroad; at present there are ten in Europe.

State Drug Clinics Close.—All clinics established by the New York State Narcotic Drug Control Commission in sixteen cities have been ordered closed, following the refusal of hospitals to receive drug addicts to complete their cures. Commissioner Walter R. Herrick plans to ask the next legislature to appropriate funds for the construction of at least three state hospitals for drug users, one in New York, one in the northern part of the state, and the third in the western part.

Personal.—Assistant Surgeon W. C. Rucker, of the United States Public Health Service, has been appointed chief quarantine officer at Balboa, Canal Zone, relieving Surgeon S. B. Grubbs.

Dr. Oscar Davis, of Anderson, has been appointed state health officer of Texas, succeeding Dr. Charles W. Goddard. Dr. Goddard has resigned to become chief of the medical staff of the University of Texas, Galveston.

Professor Frank G. Haughwout, head of the department of parasitology in the University of the Philippines, has been appointed protozoologist in the Bureau of Science, Manila.

Canadian Medical Association.—The fifty-first annual meeting of the Canadian Medical Association was held June 22nd to 25th at Vancouver, with over one hundred medical men from the United States in attendance. Dr. Murdoch Chisholm, of Halifax, was elected president. It was decided to hold the next meeting in Halifax. Among the important items of business considered were the general reorganization of the association on a more businesslike basis, the proposal to form a Canadian College of Physicians and Surgeons, the organization of the profession in its relation to the Workmen's Compensation Act, and the making of certain changes in the size and appearance of the *Canadian Medical Association Journal*. The following committee was appointed to consider the formation of a Canadian College of Physicians and Surgeons: Dr. H. A. MacCullum, of London; Dr. S. E. Moore, of Regina; Dr. F. W. Marlow, of Toronto; Dr. A. E. Garrow, of Montreal; Dr. James McKenty, of Winnipeg.

New Hospitals in China.—The *China Medical Journal* records the opening of several new hospitals in China. The Chinese Infectious Diseases Hospital in Shanghai and a new quarantine hospital at Newchwang were both opened in July. The Summer Diseases Hospital in Shanghai was opened in June.

University of Toronto Senate.—Dr. Augusta Stowe-Gullen, Dr. Charles J. C. O. Hastings, Dr. Arthur C. Hendrick, and Dr. Andrew S. Moorhead, all of Toronto, have been elected medical representatives to the senate of the University of Toronto.

Michigan Takes Tuberculosis Clinics.—The tuberculous clinics formerly supervised by the state antituberculous association have been taken over by the Michigan Department of Health, which will conduct clinics throughout the state. Dr. George H. Ramsey, formerly director of the tuberculosis pavilion in the Herman Kiefer Hospital, Detroit, will have charge of the examination of patients for tuberculosis, while under the direction of Dr. Frank L. Rose, of Jackson, children will be examined for pretuberculosis defects. The work will be under the supervision of the division of communicable diseases of the State Health Department.

Infant Mortality Report.—A statistical report of infant mortality in 269 cities of the United States has been published by the American Child Hygiene Association. The report lists the following cities with low infant mortality rates under the caption—Where Babies Have the Best Chance: Brookline, Mass., 40; Berkeley, Cal., 44; Marinette, Wis., 45; Aberdeen, Wash., 45; Everett, Mass., 47; Madison, Wis., 47; Piqua, Ohio, 48; Alameda, Cal., 49. The infant mortality rate for New York City is given at 82. Cities with particularly high infant mortality rates are: Pittsburgh, 115; Buffalo, 107; Kansas City, Mo., 103; New Bedford, Mass., 124; Camden, N. J., 121; Nashville, Tenn., 116; El Paso, 245; Knoxville, Tenn., 135; Racine, Wis., 123; Burlington, Vt., 150; Paducah, Ky., 146; Hannibal, Mo., 145.

◆

Died.

BAER.—In Philadelphia, Pa., on Saturday, September 11th, Dr. Benjamin F. Baer, aged seventy-four years.

BOOKER.—In Selma, Cal., on Friday, August 20th, Dr. Thomas A. Booker, aged forty-eight years.

BULLWINKLE.—In Brooklyn, N. Y., on Tuesday, September 14th, Dr. Henry Bullwinkle, aged fifty-four years.

COTTER.—In Brooklyn, N. Y., on Wednesday, September 15th, Dr. John Henry Cotter, aged fifty-two years.

GIBSON.—In Ramsey, N. J., on Thursday, September 16th, Dr. James T. Gibson, aged sixty-four years.

DRUM.—In Syracuse, N. Y., on Saturday, August 28th, Dr. James Henry Drum, aged fifty-one years.

GREGORY.—In Stroudsburg, Pa., on Thursday, September 9th, Dr. William Edwin Gregory, aged sixty-seven years.

HOLLAND.—In Winnipeg, Can., Dr. Robert A. Holland, of Calais, Me., aged fifty years.

JUDGE.—In Philadelphia, Pa., on Thursday, September 9th, Dr. Robert B. Judge, aged sixty-three years.

LUXFORD.—In Princess Anne, Va., on Thursday, September 9th, Dr. Thomas B. Luxford, aged forty-nine years.

MILLER.—In Omaha, Neb., Dr. George F. Miller, aged eighty-nine years.

STEARNS.—In Port Alleghany, Pa., on Tuesday, September 7th, Dr. John S. Stearns, aged seventy-two years.

Book Reviews

TREATMENT OF NEUROSES.

Treatment of the Neuroses. By ERNEST JONES, M.D. (Lond.), M. R. C. P. (Lond.), President of the British Psychoanalytical Society; Member (for England and America) of the Council of the International Congress for Medical Psychology and Psychotherapy; Honorary Member of the American Psychopathological Association. New York: William Wood & Co., 1920. Pp. viii-233.

More progress has been made in the treatment of the neuroses than in any other branch of medicine, and among the most progressive of the workers in this branch of medicine is Dr. Ernest Jones. The book which he presents on the treatment of the neuroses is an elaboration of the section devoted to this subject in Jelliffe and White's *Modern Treatment of Nervous and Mental Diseases*.

One of the interesting features of Jones's book is his tolerance toward other more obsolete methods of treatment. He traces step by step the important measures that have replaced other methods in the evolutionary progress that has been made in this branch of medicine. He first considers, in a broad way, the handling of hysterical subjects, analyzing the various physiological means that have been used. The Weir Mitchell treatment is described in detail. The author then takes up the various psychological methods and divides them into three principal divisions, viz., suggestion, reeducation, and psychoanalysis. Under suggestion he places various types of hypnotism. In an exceedingly simple manner he shows the mechanism underlying these processes and how they fall short of the ultimate aim.

The chapter on reeducation is more complete. This method of treatment, while it shows much progress over the methods previously used, still does not suffice. A deeper search is made for the pathogenic factors in place of being content with dealing with the results of the pathological condition. Therefore from the point of view of stability this system is superior to that of suggestion. In searching for causative factors it was found necessary to go beneath the surface. The reactions of the patients are not due to the stimuli which are seen on the surface but to traumatic shocks received at other periods of the patient's life and the emotional reactions are caused by the present stimulus bringing back the former effects, which may be forgotten by the patient, but which continue to exist in his unconscious and retain their vitality in an amazing manner.

Finally psychoanalysis, the method devised by Freud, is discussed. The method which was first intended for the treatment of hysteria has been put to wider application and at present is successfully used in many other forms of psychoneuroses. Fundamental problems of psychology have undergone revision and the fields of mythology, folklore, philology, and anthropology have been examined by this new science.

Nevertheless it has remained the treatment of choice among progressive neurologists for hysteria and similar neuroses. The findings of reeducational methods are in the main confirmed by Freud. It is granted that every hysterical symptom has for its basis an amnesia. It is acknowledged that the un-

conscious functioning of unconscious material is an important factor in the theory, but Freud does not emphasize the factor of a vague constitutional inferiority as being a secondary factor. The inability of the patient to make adjustments to his surroundings due to his inability to orient himself to the situation as it exists in his own unconscious is largely responsible for the disordered state.

Jones shows how psychoanalysis is the method of choice as it is the most thorough method of all. He carefully explains the technic of transference, the analysis of the dream, and other unconscious material, how use is made of free association in tracing back complexes, and how the patient gradually becomes acquainted with himself by the unraveling of his unconscious which has been hidden from him and yet has created the havoc which led to the neuroses.

Some space is also devoted to the anxiety neuroses, anxiety hysteria, neurasthenia, obsessions, hypochondria, and the traumatic neuroses. Other topics of a forensic nature are also discussed.

The book is extremely well written and unlike many books on neurological subjects it does not run away from the practitioner by the use of highly technical phrases. Dr. Jones has been careful to keep it within the reach of everyone who would be likely to read the book and at the same time he has not in any way lost the import of any of the material presented. It is seldom that one can say in speaking of a medical text book that it may be read and enjoyed.

GOTTFRIED KELLER.

Gottfried Keller. Psychoanalyse des Dichters Seiner Gestalten und Motive. Von Dr. EDUARD HITSCHMANN. Wien, Austria: Internationaler Psychoanalytischer Verlag, G. M. B. H., 1919. Pp. vii-125.

Poets afford a peculiarly instructive study of what man is and why he is hindered in being more than he is. Poets are poets in that they are compelled from within to reveal what constitutes a human life, with its limitations. Psychoanalysis turns fearless eyes upon these inner things and a sympathetic ear to these self-revealing voices. Through a psychoanalytical study of the poets, therefore, knowledge is gained which has a manifold value, the poet himself is better understood and comes closer into the common brotherhood of striving and divided success. His message is fraught with more universal meaning. The limitations which mark his work, which often are but the warring of elements of greatness and power, are the wholesome lessons directed upon all lives. Especially in the spirit of today they call for an invigorating search into our own lives to understand our failures, to find only in some other form the same inner psychic causes for limitation and imperfection everywhere. In this way they act as reproachful stimuli to a better guidance of child nature than the race has yet deemed worth while.

It is this last consideration which is urgently forced upon one from the psychoanalytical study of Gottfried Keller, poet and artist, and a striking figure in German literature. For he had greatness

and the limitation which his fundamental childish fixations put upon him were in themselves largely the starting point, after a good deal of delay, of the forms his creative activity made its own. Yet his work was so much less freely expressive than it might have been, the imprint of his personal conflicts was so great, his personal life fell so far short of that of the healthy man, that one is almost oppressed with the sense of burdening waste which a bad early adjustment can work in any life. On the other hand, one is heartened by the innate resoluteness of the human psyche which turns to an expression which, more or less successfully, frees the burden in the poet and in those to whom he speaks.

It is not an idle surmise, this discovery of the source of incompleteness in artistic power and of failure in life in Keller's early years. He has given testimony in his own reminiscences, though he was a silent, reserved man, as well as in his manner of life. His works, particularly his *Grüner Heinrich*, are autobiographical, not so much of external events as of the attitudes and inner experiences which they contain. So also are the years of groping after his work and the final slow development of it. Something prevented him from devoting his life to painting the human figure, and landscape painting passed over into word painting and the deeper development of epic writing.

This history, with its close reference to the psychic life of Gottfried Keller, is sketched in this attractive volume of Hirschmann. One by one the various infantile elements are revealed as playing a conspicuous part in his life and his work. It would seem that Hirschmann might have entered somewhat more enthusiastically into his subject and carried his readers more completely into the poet's psychic experience. Perhaps this is due in part to a lack of familiarity with his works on the part of the English reader such as Hirschmann may presuppose with his readers nearer home. The book, in spite of its slightly sketchy character, forms a welcome addition to the growing number of psychoanalytical studies of our creative writers. It reveals as such that knowledge of human life which is needed more and yet more and it stimulates to a use of such knowledge. Thus failure may be prevented and success increased.

A MODERN DON QUIXOTE.

*Youth and Egotism.** By PIO BAROJA. Translated from the Spanish by JACOB S. FASSETT, JR., and FRANCES L. PHILLIPS. Edited with Introduction by H. L. MENCKEN. New York: Alfred A. Knopf, 1920. Pp. v-265.

A most refreshing book. It is rather difficult to agree with a man like Baroja who disagrees with almost everybody and everything but at least he is to be admired for his candor. He deals, in this small volume, with all manner of things and most fearlessly. Politics, literature, art, religion, and men are all inspected by the gaze of this vigorous Basque. Basque he is and physician and baker he was, but through it all he has remained a rebel. In his analysis, if such it may be called, he uses an acid that bites deeply, but no matter how far-reaching his deductions one feels that he is sincerely searching for the truth: He loathes the complacent bourgeois, with their self-satisfaction and

their tolerance of orders and things they know nothing about. He hates bitterly all of the instrumentalities that help keep people in darkness. He feels that they are his enemies, for they are the enemies of progress.

He has a few literary favorites, including our own Poe. With Dostoevsky and Nietzsche he finds no fault, but few others are immune from his withering criticism. Shakespeare, Molière, Cervantes, are all flayed. Then he attacks Goethe, Hugo, Chateaubriand, Stendhal and Balzac and in truth it must be told he finds their weaknesses with precision. He is daring in his attacks and with a few acrid words closes the incident. For the critic he finds little praise and so he burns his way through, respecting little but striving to maintain his own self-respect. It is a small book but it would be difficult to fall asleep reading it. Of great interest to us is the fact that at one time he was a physician. This, however, should not account for his bitterness, for they do not all get that way.

BREAKERS AHEAD.

Feminism and Sex Extinction. By ARABELLA KENEALY, L. R. C. P. (Dublin). New York: E. P. Dutton & Co., 1920. Pp. vii-313.

Arabella Kenealy draws three vivid pictures: What woman was, what woman is, and what she will become. Two fates await her, feminism and feministicism, unless she rids herself of a contempt for functions and duties purely hers. Moreover, she is handicapped every month for two or three days by a certain amount of weakness and pain, and every man knows her temper is affected at such times. Many months are consumed in childbearing, and still more months in childrearing. It is no use quoting the rude health of savages. Mrs. Savage has not to clothe her offspring; nor have a washing day, nor go shopping. The modern woman can get all sorts of appliances for lessening the care of children, but no one has yet borne an automatic baby whose crying could be turned off and sleep turned on. "The hand that rocks the cradle rules the world." Well, she may have an automatic hand to do the rocking, but the psychologists have already condemned rocking as an evil practice. Girls can refuse to have babies. The law can exert no compulsion, but that would result in extinction of the civilized stock and domination by savage tribes. This craze to do man's work will end in the emasculation of men. This desire to figure in the senate "far from stiffening the manly calibre of weak men in it will still further enervate them. Women should have a house of their own, wherein to foster the interests of women and children mainly." Members of either sex are not capable of doing their best work while in association with the other. Sex rivalries are stirred, sex ascendancy engendered. Besides, man inherits from his mother the quatum of "woman apprehension, foresight and altruism required to present the woman's bent and viewpoint. More of it would be superfluous." The author thinks the huge numerical preponderance of women must presently swamp masculine initiative in state affairs, unless the political functions of the sexes are separated.

Also that women are swiftly coming up abreast of men and threaten to outdistance them, but the emotions and devotions, purity, sweetness, patience, forbearance, loveableness, courtesies and graces have fallen out of culture. The yielding by man to the other sex of masculine essential rights and obligations is a symptom of declining virility, physical and mental. So far the author does not draw flattering pictures. Here is one which may arouse wholesome alarm:

One serious aspect of feminism is that woman in gaining mannishness is losing beauty. The faces even of our handsomest women are preeminently bold, sophisticated, clever without sweetness. The eyes are cold and critical and challenging. The naturally delicate contours of chin and cheek have deteriorated to the crude and heavy lower jaws of those desexed by masculinity. Our schoolgirls and workgirls are, biologically speaking, spoiled copies of men. The neuter state shows in the faces of many women. In the eyes of young women of strenuous pursuits the characteristic sterile glint, part boldness, part antagonism, is common.

But how about the ultrafeminine who plunge in violent recoil into social frivolities, vanities, dissipations, pranks, intrigues, excesses? Two extreme camps are being formed, the mannish and strenuous and the overfeminized and purposeless, more or less idle and frivolous, selfishly absorbed in clothes, in luxury and pleasure; exacting masculine tribute in mind and kind, and since every privilege is shared by both sides—liberty, latchkeys and general latitude. Between the two extremes stand the natural, noble and invaluable moderates, normal women content to be normal women and to fulfil the destined rôle of such. Man, however, seems to prefer the feminist.

There are other evils growing. Our school and college girls make heroes of their own sex who excel in manly sports, they worship the man in them; also strong attachments between the sexes, man for man, woman for woman, are intensifying. Women are attracted by mannish traits in their sex, men by effeminate men who possess feminine traits of sympathy and sentiment. Both sexes are lapsing towards a neuterdom, evidence of sex decline. The present day decline in parental impulse and affection shows it. To quote Havelock Ellis: "These weak chinned, neurotic young men are no match at all for the heavy jawed resolute young women feminist methods are creating. The yielding to women of masculine rights is a symptom of declining virility. Equality in all things yielded, pride in himself, in his work, gone, he will descend to the state of the decadent savage who keeps as many wives to work for him as their work for him enables him to keep."

Moreover, overworked woman may impair the constitutional vigor of man, while she works with him. She is kept up by nervous excitement, by strong tea or drugs. In short, woman is fussy. In a stress of work she will work on with crimson cheeks and growing irritation, while man will put on his hat and calmly resort to the nearest lunch room. Women by their eternal high pressure as heads of departments are making nervous wrecks

of the men. "Nervous depletion caused by working wives has doubtless much to do with the inanition and depression now crippling our industrial output."

Can the man keep his chivalry and meet the woman on equal terms? He will still see her as mother, wife or love (mistress). He cannot disregard her involuntary looking to him for aid. How it will be when men realize what feminism means we cannot tell. Women's abnormal mentality added to their impulsiveness impels them to break loose from those bonds of affection, tradition and aspiration which are their safeguards. Power, which steadies all but weak men, too often drives women to destruction.

So far we have quoted the author in giving her fears for the future. What does she want? She would have the sexes work in unison but in different areas, apart from and independent of the other. Women are to bear children, suckle them, rear them, and those who have none are to aid them in securing what every child should have. The work a mother has to do in pregnancy should not tend to damage the child. The question of abolishing the legal contract in marriage deals slashing blows at modern ideas. If love is the sole bond then the waning of love must release from the bondage. But we doubt if any man will want to marry the terrible mannish woman. "More and more the hidden male emerges from the female wreckage." Woman has been striving after masculinity all these years. She has gained the gift, but at a tremendous price.

It would take many pages to give an idea of Miss Kenealy's book. She deals with the evolution of sex, the female brain, sex instincts; how feminist doctrines and practice destroy womanly attributes, morale and progress. There is much that is true and the present attitude of young men confirms it, but we cannot see the terrible results foretold; rather, woman should be considered drunk with her new power, of which she will tire when she is required to face man's obligations as well as his privileges.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

ANNUAL REPORT OF THE DEPARTMENT OF HEALTH. City of Newark, N. J. (Department of Public Affairs). Illustrated. Newark: The Essex Press. Pp. ix-240.

THE FOUR JUST MEN. By EDGAR WALLACE, Author of *The Clue of the Twisted Candle*, *The Secret House*, *Green Rust*, etc. Boston: Small, Maynard & Co. Pp. i-310.

VACCINATION IN THE TROPICS. By W. G. KIND, C. I. E., Colonel, I. M. S. (Retired); Late Sanitary Commissioner with the Government of Madras, and Superintendent General of Vaccination and Inspector General of Civil Hospitals in Burma. Illustrated. London: Tropical Diseases Bureau, 1920. Pp. vi-64.

THE DEVELOPMENT OF THE HUMAN BODY. A Manual of Human Embryology. By J. PLAYFAIR McMURRICH, A. M., Ph.D., LL.D., Professor of Anatomy in the University of Toronto; Formerly Professor of Anatomy in the University of Michigan. Sixth Edition, Revised and Enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1920. Pp. x-501.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Intravenous Mercuric Iodide in Syphilis.—R. L. Spittel (*Lancet*, February 14, 1920), working on the assumption that intravenous mercury and iodide would give even more favorable results in conjunction with arsenic preparations than does the intramuscular medication, has given over four thousand injections of the following preparation into the vein during the last four years:

Mercuric iodide,	50 grains
Sodium—or potassium—iodide,	8 dr.
Phenolphthalein, 0.5 per cent. sol.,	20 minims
Sodium hydrate, 25 per cent. sol.,	about 2 dr.
Distilled water,	to 40 oz.

The sodium hydrate is added last and slowly. When the neutral point is reached it is put in drop by drop until a clear pink color is reached. The solution keeps indefinitely but tends to become decolorized. It may always be restored to normal by the addition of more sodium hydrate.

Eight to twelve c.c. of this solution, diluted to twice the amount and filtered, is the dose to be given into the vein. The reaction to small doses is little or none, but if larger doses are given chills, fever, and abdominal pains with diarrhea may result. The symptoms of mercurialism must of course be watched for. The results of such injections are much quicker than when the ordinary methods are used, both from the standpoint of the Wassermann reaction and from the effects on syphilitic lesions. The course of treatment consists of five or six injections of salvarsan and a similar number of mercuric iodide injections given every seven to ten days, alternately or in whatever sequence seems best. Prolonged treatment with mercury by mouth or inunction should be continued for a year or so even if the serological test is negative, as a matter of precaution.

Frontal Sinus Drainage.—Max Unger (*American Journal of Surgery*, May, 1920) employed the following technic in frontal sinus drainage: The nasal mucosa is anesthetized and the frontal sinus is probed. The probe is first used by itself to determine the size and the direction of the fronto-nasal opening. If the opening is obstructed by the middle turbinate this must be removed. The size and direction of the opening having been ascertained, the probe is then pushed through the lumen of the proper sized catheter to its end. The probe, encased in the catheter, is then reinserted in the frontal sinus. The catheter is held loosely by the fingers of one hand and the probe is gently withdrawn by the other, leaving the catheter *in situ*. The catheter is then grasped near its entrance into the opening with a nasal forceps and pushed further into the frontal sinus as far as it will easily go. Being flexible it will pass over projections that will block a metal catheter. The lower end of the catheter is then cut off intranasally, so that the remaining portion rests on the floor of the nose. At the end of this procedure there is then left a tube about two and a half inches in length, extending from the floor

of the nose up into the frontal sinus. This tube is left in place for one to two days, when it is removed and replaced by another. Before the tube is replaced the sinus can be irrigated. The catheter is cut three and a half inches long to begin with because its lower end will then project from the nose after its tip is in the sinus and furnish a place for holding it when the carrying probe is withdrawn. If linen or silk catheters are used, they should be dipped into hot water before being inserted into the nose, in order to make them softer.

Intravenous Injection of Hypertonic Glucose Solution in Chronic Nephritis with Azotemia.—F. Rathery and H. Boucheron (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris*, January 22, 1920) calls attention to the fact that in chronic nephritis with nitrogen accumulation in the blood intravenous injection of thirty per cent. glucose solution fails to exert its usual diuretic effect. Careful clinical tests showed that such injections caused, in these cases, a diminution of urinary output, including that of total nitrogen, urea, sodium chloride, and ammonia. In two patients with pronounced azotemia the latter was made considerably worse by the measure, and in one case with moderate azotemia the blood urea was temporarily increased. These changes were often more marked two or three days after the glucose injection than on the next day.

Surgical Treatment of Acute Empyema by Valve Drainage.—William Reid Morrison (*Boston Medical and Surgical Journal*, April 8, 1920) sums up as follows the advantages of valve drainage: An indirect valve opening is made in the chest. A valve made of the living tissues is the most efficient type because it does not get out of order; mechanical valves in aspirating trocars, and devices, such as a rubber dam pasted on three sides of a wound, are less desirable. In cases of pneumococcus and mixed infection, masses of fibrin, detritus and pus are readily removed. The gloved finger is able to break up any recently formed adhesions which may anchor the lung and prevent its expansion. Foreign bodies, if any, may be extracted. Collapse of the lung, mediastinal flapping and pneumothorax may be avoided, with more rapid convalescence, avoiding chronic empyema. He further says that no empyema should be operated on before a careful consultation with the medical man in charge of the case. Too early or too late operation is to be avoided; the duration, extent and virulence of the process in the lung, embarrassment of respiration from large amounts of fluid, and progress of the case are the factors that influence the surgeon's judgment. Local, combined with paravertebral injection, is the anesthetic of choice. In pneumococcus cases, valve drainage with pleurotomy or rib resection with indirect drainage of the chest may be used to advantage. In streptococcus cases, particularly in hemolytic streptococcus

infection, Kenyon's tube, with or without suction, or repeated aspirations, may be of value, allowing no air to enter the chest. The surgical treatment should be supplemented by careful attention to a high caloric diet, principally milk and raw eggs for the first few days. Medication in the form of digitalis leaves or other cardiac stimulants to tide over the lung infection, morphine for pain, tincture of nux vomica as an appetizer, and later iron are given as indicated. Good nursing, warmth, and fresh air are essential. Early bottle blowing and later proper gymnastic exercises are desirable to stimulate lung and chest expansion and prevent deformity. A half sitting position aids respiration and drainage after operation. A direct opening into the pleural cavity should not be made in acute empyemata. The writer has not been favorably impressed by the use of serological treatment.

General Anesthesia.—A. R. Egaña (*Semana Medica*, April 29, 1920) sums a lengthy article by stating that for short operations, where absolute muscular relaxation is not necessary, nitrous oxide and oxygen is the anesthetic of choice. He prefers Gwathmey's apparatus as it conforms to the conditions required, namely, easy graduation of the proportion of the gases, valves of easy access, easy and rapid utilization of ether when required, and warming of the anesthetic vapor.

Where muscular relaxation is imperative and especially in abdominal surgery, the nitrous oxide-ether sequence is the best. Chloroform owing to its dangers is inferior to ether, with which, however, it may be readily combined.

The open or semiopen method of administering ether is advisable except when the intrapharyngeal route is necessitated, as in operations on the neck, the face, the skull or in the ventral position. The intratracheal route is useful in operations on the thorax, while rectal administration of ether in a five per cent. solution in oil is quite feasible.

Severe Cerebral Toxemia After Intravenous Novarsenobillon.—R. J. G. Parnell and S. F. Dudley (*Lancet*, January 24, 1920) report a case of secondary syphilis which was being treated with this arsenic compound. The first dose was 0.45 gm. producing no reaction and the second, 0.9 gm. given four days later produced no reaction until fifty-six hours after injection into the vein. The patient began to vomit and during the next three days he had a series of seven epileptiform convulsions with unconsciousness, biting of the tongue, incontinence of urine and feces, together with a macular eruption on the skin, marked cyanosis and failing pulse. Adrenalin injections, calomel in hourly doses, and lumbar puncture failed to relieve the symptoms, so oxygen inhalations were given to combat the evident anoxemia and caffeine 0.2 gm. with urotropin 1.5 gm. in 15 c.c. of sterile distilled water was given, in accordance with the work of H. Michel, to relieve the maniacal state, probably through the great diuresis resulting. Five hours after the injection was begun and the oxygen inhalations were started the patient had become entirely rational and thereafter made an uneventful recovery, though he suffered from a partial amnesia for fourteen days.

Treatment of Tuberculous Glands of the Neck.

—A. Wiese Hammer (*Medical Council*, June, 1920) thinks that not every case demands surgical interference. In cases where the affection seems to recede at times the patients recover under proper hygienic treatment supplemented by medical measures. X ray treatments tend to produce fibrous tissue which is a serious obstacle to operation at a later date. In obstinate cases operative measures offer two great advantages, viz., the prevention of sinus formation and of unsightly cicatricial formation and the elimination of tuberculous infection from the body. Operation to be successful must be radical; partial removal is useless. The usual incision is along the whole posterior length of the sterno mastoid muscle from the mastoid process to the clavicle. Hammer prefers incisions which follow the circular furrows on the neck, thus leaving far less unsightly scars than by the linear methods of incision. In any incision the skin and platysma are reflected, bringing the sterno mastoid into view, which is then divided. Great care must be exercised against injuring the internal jugular vein, and the occurrence of air embolism. The glands are stripped by blunt dissection from the subclavian and internal jugular veins, and from the space posterior toward the trapezius muscle, care being taken not to wound the thoracic duct.

Chlorine Antiseptic.—Walter Estell Lee (*Annals of Surgery*, June, 1920) gives the clinical uses of sodium hypochlorite, chloramine-T, and dichloramine-T as follows:

1. The direct germicidal effect of all the chlorine antiseptics is dependent upon the liberation of their chlorine and the combination of this chlorine with bacterial protein.

2. The rapidity with which the hypochlorite solutions liberate their chlorine necessitates, in order to avoid the destruction of living tissues, the presence of large masses of available protein (devitalized tissues and profuse wound exudate) or the use of such dilute solutions that a safe margin in the relative masses of the active chlorine and available protein is insured. Thus the usable strengths of hypochlorite solutions, which should be less than 0.5 per cent., liberate such a small mass of chlorine that their direct germicidal effect is almost negligible. But, unlike the other chlorine antiseptics, they exert a very definite indirect germicidal effect by the formation of hydroxides which act as solvents of the culture material provided by devitalized tissues and wound exudate.

3. The synthetic chloramines are more stable compounds of chlorine than the hypochlorites and therefore can be used in greater concentrations or larger germicidal masses. They act practically as reservoirs from which chlorine is slowly and automatically given off as the tissues present the necessary reacting substances.

4. The hypochlorite solutions are indicated where there are large masses of dead and devitalized tissues or profuse tissue exudate which cannot be removed by mechanical means. They should not be used where such as are not present or applied to tissues poorly supplied with blood, tendons or cartilage.

5. The chloramines are indicated where there is but little, if any, dead tissue, and where the wound exudate is moderate in amount. Their only value is as a germicide. When in the human tissues, they slowly liberate their chlorine over a period of from three to twenty-four hours and in sufficient quantities to automatically unite with the bacterial and other proteins presented by the wounds.

Operation for Urethral Strictures.—M. Stern (*International Journal of Surgery*, April, 1920) states that as all, or nearly all, strictures occur anterior to the superficial layer of the triangular ligament, this operation can easily reach them. Extravasation of urine or infiltrating abscesses are not to be feared in a surgical procedure which does not disturb the membranous or prostatic urethra lying posterior to the triangular ligament. An operation which is directed precisely to the diseased area, and which does not inflict injury to any other part of the urethra, must be conceived as a logical step to a cure, and as superior to procedures heretofore in vogue.

High Forceps Operation; Version and Cæsarean Section.—William B. Doherty (*International Journal of Surgery*, April, 1920) believes that Cæsarean section is rapidly gaining favor in the management of labor in the presence of pelvic distortion among the most conservative obstetricians and surgeons, yet in these borderline cases, unless there is a marked neurotic and debilitated condition of the woman, it is better that she go into labor and the measures advocated be attempted before resorting to the Cæsarean operation. With capable surgeons and maternity hospitals which can now be reached in a few minutes and the improved technic which obtains, the chances for the safety of the woman and her child in a case of pelvic contraction are far better than they were a few years ago.

The Clinical Importance of Anatomical Anomalies in Biliary Surgery.—Daniel N. Eisendrath (*Boston Medical and Surgical Journal*, June 3, 1920) says that recent anatomical studies have shown that the normal angular mode of union of the cystic and hepatic ducts is present in only seventy-five per cent. of the cases; that the cystic artery is a single structure and has its generally accepted origin in only about eighty-eight per cent.; and that there are two cystic arteries in twelve per cent. of individuals. He describes with illustrations the variations in the relation of the right hepatic artery to the main hepatic duct; variations of the gastroduodenal artery; anomalies in origin of a single cystic artery; relation of a single cystic artery to the main hepatic duct; two cystic arteries which may both arise from the right hepatic, one from the right hepatic and one from the gastroduodenal artery, one from the right hepatic and the other from the main hepatic, or both from the left hepatic; variations in the course and mode of union of the cystic and hepatic ducts, and variations in the hepatic ducts. Some of these variations in anatomical structure are of much importance, for their presence may give rise to accidents during operation.

Treatment of Fracture of the Ulna with Dislocation of the Head of the Radius.—C. Dujarier and P. Mathieu (*Paris médical*, April 10, 1920), from experience with a personal case and study of the literature, have reached the conclusion that reduction of the radial head alone in recent cases is not always followed by a sufficient degree of reduction of the ulnar fracture, so that actual osteosynthesis is advisable; indeed, persistent shortening of the ulna would in itself predispose to recurrence of the radial dislocation. Reduction of the ulnar fracture alone does not generally result in reduction of the radial dislocation. The capsule often becomes interposed beneath the radial head, requiring operation upon the humeroradial joint. Evidently two operations, one upon the radial dislocation and the other upon the ulnar fracture, are required in these cases. Abadie thinks that the reduction of the ulnar fracture should precede the reduction of the luxation, the latter being facilitated by the former procedure. The authors believe, however, that in recent fractures, i. e., fractures in which the ulna is not yet in process of consolidation in a faulty position, it is well first to reduce the radial head by arthrotomy, remove any interposed portion of capsule, and restore the joint by capsulorrhaphy. Reduction and fixation of the ulnar fracture are thereby greatly simplified. In long standing cases, in which the ulna has healed in a faulty position, with angular deformity and overriding, it would perhaps be better to begin by liberating the ulnar fragments, next reduce the radial luxation, and finally proceed to operative fixation of the ulna. Resection of the head of the radius should not be resorted to until after an open restoration of the joint has been attempted.

Application of War Methods to Civil Practice.—A. Bowlby (*Lancet*, January 17, 1920) discusses the significance of the surgical discoveries of the war as regards treatment in civil practice. Shock, being due in part to privations suffered by the soldier before injury, is not so frequently found in civil life but when it is present it must be treated with warmth, fluids, rest, and morphine. It must be guarded against by the proper care of the patient during the period of temporary treatment as with splints, to prevent further damage of tissue or unnecessary pain during transportation. It is possible to train orderlies to prepare a fractured femur for transportation with the Thomas outfit more suitably than the trained surgeon could have done it before the war. If the patient be in shock and unable to retain fluids by mouth, rectal administration is indicated, as fluids absorbed by the gastrointestinal mucosa are of more lasting benefit than those put into the vein. *In extremis*, however, intravenous fluids are necessary and in the opinion of the writer, six per cent. gum arabic solution in saline is the most useful of all except blood itself.

Where anesthesia must be used shortly after recovery from the more urgent symptoms of shock, it was found that ether, though unlikely to cause pulmonary conditions or vomiting when warmed, did produce a dangerous and prolonged lowering of blood pressure. The most satisfactory results were obtained with nitrous oxide and oxygen com-

bined with local infiltration of the incision region, particularly in abdominal operations.

The advance in treatment of fractures is summed up in the statement that during the last half of the war, fractures were treated by suspension and extension so that the circulation, nourishment, and mobility of the extremity were maintained as far as possible. Regarding wound infections, the points emphasized are, 1, the uselessness of antiseptics in grossly infected wounds; 2, the importance of excision of damaged tissues around the wound with either primary or delayed primary suture; 3, the great danger of secondary infection of the wound if not quickly sutured; 4, the value of irrigation, as by the Carrel method if properly carried out, in the cure of suppurating wounds.

Electrical Osmosis of the Eye.—Roux, P. Girard, and Morax (*Paris médical*, April 10, 1920) report experimental work in which a cup containing solution of salt was placed as positive electrode over the cornea of a rabbit and a negative electrode placed over the back of the neck. Upon passing a current, increased intraocular tension results if the solution in the cup contains magnesium sulphate. If, on the other hand, the solution is one of barium chloride, reduction of intraocular tension occurs and the eye shrivels. The opposite eye and the eyes of another animal were used as controls. The authors hope by application of this principle to obtain useful therapeutic effects in certain eye affections.

Splints Used for Peripheral Nerve Cases at the U. S. Army General Hospital No. 11.—Robin C. Bureki (*Archives of Neurology and Psychiatry*, February, 1920) reports that at Army General Hospital No. 11 it was decided that the splints which had been applied in the nerve cases had numerous disadvantages. They were heavy and cumbersome and in a large number of cases were retarding rather than aiding recovery. With these faults in mind, each lesion was studied from the standpoint of splints, and a special group of splints was designed for each type of case. These were then tried out and the one found by actual practice to be the more satisfactory was adopted as a standard splint for a given lesion.

Transplantation of Kidney and Ovary.—Carleton Dederer (*Surgery, Gynecology and Obstetrics*, July, 1920) presents the following conclusions from experimental transplant.

1. A homotransplanted kidney during twenty-six days has passed the same functional tests as are required of normal kidneys.

2. In dogs of the same litter a homotransplanted kidney and ovary lived for twenty-six days. Pathological examination showed that the organs reacted to the severe constitutional infection, distemper, in a manner similar to that in which the animal's own organs reacted.

3. Phenolsulphonephthalein after being injected into the external saphenous vein began to be excreted from a homotransplanted kidney in two minutes and forty seconds.

4. It is possible in making a homotransplantation of the kidney to get a satisfactory arterial anastomosis by suture when the renal artery is less than a millimetre in diameter.

Submucous Resection of Nasal Septum.—W. D. Dunning (*American Journal of Surgery*, May 1920) states that the advantage of the submucous operation over other operations for deflection are:

1. That no mucous membrane has been destroyed.
2. That spurs and deflections have been entirely removed with the thickening of the septum.

3. That the ridge of cartilage which is wedged in between the lateral cartilage has not been interfered with, and there is absolutely no danger of a falling or saddleback nose.

Mercury in the Treatment of Syphilis.—Louis D. Smith (*Illinois Medical Journal*, May, 1920) has used mercurosal (or disodium mercuri salicylacetate) with satisfactory results. This salt is derived from mercuric acetate and salicylacetic acid and contains forty-four per cent. metallic mercury by weight. He has demonstrated that this preparation, in a dosage of five c.c. containing over one-half grain of mercury, answers the question of mercury medication very well, as by its use it is possible to employ a larger dosage of mercury more safely and more painlessly than by any other method.

The Use of Radium in Gynecology.—William C. Gewin (*Southern Medical Journal*, July, 1920) says that radium is the treatment of choice, a, in cases of menorrhagia of menopause not associated with large fibroid tumors and in which the possibility of carcinoma has been eliminated; b, in cases of menorrhagia in patients between thirty-five and forty years of age who have small mucous fibroid tumors without malignancy; c, in cases of myoma in which operation is contraindicated; d, in cases of menorrhagia in young persons resistant to all medical treatment, and in all cases with a malignant tendency; after operations for cancer; in all inoperable cancers to relieve pain, eradicate odor and stop hemorrhage. Radium will render operable many inoperable cases, and is practically the only means of relief in cases of recurrent carcinoma of the uterus.

Value of Radium in the Treatment of Bladder Tumors.—J. T. Gerachty (*Southern Medical Journal*, July, 1920) says that while benign and malignant papilloma and the early papillary carcinoma disappear under the influence of radium, the infiltrating types have proved very resistant to this agent. Therefore, when the infiltrating character of the growth has been determined, and when the tumor is sufficiently localized to permit of complete removal, he performs a radical resection. Following the removal of an infiltrating papillary carcinoma, cystoscopy should be done at an early date, as the not infrequent recurrences will yield promptly in many instances to radium, notwithstanding the resistance of the primary tumor. The use of radium has not diminished the tendency of bladder tumors to recur, but the recurrence responds to radium in most cases. Radium has proved to be a valuable aid in the treatment of bladder tumors, and, while the results obtained in the infiltrating types are far from satisfactory, improved technic whereby more intensive radiation may be safely accomplished offers a more encouraging outlook in the future handling of these cases.

SECTION IN MEDICAL EDUCATION

The President, Sir GEORGE NEWMAN, in the Chair.

President's Address.—Sir GEORGE NEWMAN, chief adviser to the Ministry of Health, said that the establishment of clinical teaching units was but an expression of the growth of integration. The clinical unit was merely a matter of convenient arrangement by which three general advantages were secured. 1. The clinical teacher devoted a regular and substantial portion of his time to his teaching work and instead of being casual, secondary, or spasmodic, it became his chief task; for the student instruction in clinical medicine and surgery was thus systematized, thorough, and always available. 2. The unit consisted of a staff of competent men working as a team who pooled their experience—the physician, the assistant physician, the resident physician and the house physician, wards, outpatient department, laboratory, auxiliary departments for special forms of treatment, all in a composite unit. 3. There was full integration of the science and art of medicine and surgery, the teaching of which could thus be raised to university standard. There was the association of research with study, and the study itself was intimate and intensive; it should comprehend Sir James Mackenzie's subjective and associated phenomena, it should investigate the mechanism of symptoms, and it should follow end results back to their origins. At Edinburgh there were seven surgeons, with Sir Harold Stiles as Regius professor of clinical surgery, he himself an assistant surgeon, a clinical tutor, and a house surgeon. The unit contained forty-four beds, outpatients, and laboratory accommodation. The work of the week comprised ward clinics, systematic clinical lectures, tutorial classes, and operations.

Sir George said that, speaking generally, the main reforms needed in the medical curriculum were four: 1. A lightening of the curriculum at both ends; in other words, fuller preparation in science before entrance to the medical school, and a postponement of instruction in certain specialties and in general practice to the postgraduate period in order to provide continued education of the qualified man, teaching which required organization on the basis of professoriate, hospital, laboratory and clinical experience, which may well be organized in such cooperative practitioner clinics as those devised by Sir James Mackenzie at St. Andrews. This question of lightening without lengthening the curriculum was of cardinal importance. Much of our trouble arose from the overloaded condition of the five years. There was insufficient time allowed for true study, for digestion and assimilation. He suggested several remedial steps and remarked that the true criterion of training in medicine was equipment for life, not preparation for an examination. 2. A

fuller study of the sciences preliminary to medicine and a nearer application of these subjects to clinical work. Above all, there was great need for biology, anatomy and physiology. 3. Development of clinical teaching of university standard, particularly in relation to the beginnings of disease, the child and the outpatient; the science of prevention; the closer integration of various forms of clinical practice and of clinical with intermediate study; concentration on the protean diseases of tuberculosis, malaria, venereal and malignant diseases; an understanding of the social side of therapeutics, environment, diet, occupation and the use of physical agents, as well as the social aspects of disease. Some of this should clearly come after graduation. 4. There was need of further state aid, though with a minimum of state control. The cost of proper medical training had now risen beyond the means of the average man and yet it was in the interest of the state to secure well equipped doctors. To provide a satisfactory medical education there were needed: a, better teachers and better paid teachers; b, clinical units; c, improved laboratory accommodation and better equipment; d, an extension of hospital and clinic facilities for teaching. All this meant money and organization, both of which had been lacking in the past. The education of the medical man was no longer merely a professional interest. It was of national concern, for the health of the people was the principal asset of the state. Sir George said that while some advocate removal of preliminary science from the curriculum, he was convinced that it was more essential than ever. Physics, chemistry and biology were key subjects, absolutely fundamental. Newman was particularly insistent upon the claims of biology. The two chief needs of English medicine were a, the full integration of its several branches and constituent parts, and b, its new relationship to sociology. Man was a social animal and all disease had its social aspect. The student must be taught this, he must learn to use his stock of knowledge socially as well as logically. The great problems which would face him in practice had a social setting—tuberculosis, infant mortality, rickets, physical impairment, venereal diseases, heart disease, mental abnormality, all bore a highly complex relation to society, industry and government.

Mr. SYDNEY J. HICKSON, F. R. S., professor of zoology in the University of Manchester, made some caustic remarks with regard to the standard of general education of medical students. He declared that the real difficulty with all English science classes in the first year of medical study is caused by a minority, but often a substantial minority, of students with a lower standard of school education. Too many students were entered by the medical schools whose vocabulary and facility in composition were not sufficient to enable them to profit by the lecture system, or to express what little they had learned in a written examination. Further, and still more important, many students did not possess a mind trained to remember or to think. It was these students who acted

as a drag upon the machine and so hindered the development of medical courses in science on the lines which would be most useful for medical men. The first step in this direction was to insist that the lowest standard accepted for registration should be that of the matriculation examination of the British universities. The five years' study of a medical student was not enough to enable him to grasp all the knowledge that it was desirable or even necessary for him to have as a qualified man.

MR. ARTHUR KEITH, F. R. S., Hunterian professor, Royal College of Surgeons of England, thought it was not the student who was at fault but the teachers and that the problem to be faced was not how to improve the education of the medical student but how to educate and reform his teachers. In fact the real problem to be solved was how a staff of specialist teachers was to produce an army of effective medical practitioners. Mr. Keith thought the specialist teacher should keep up his knowledge of general medicine and that at the great medical schools every teaching anatomist and physiologist should have to hold occasional clinical appointments up to their thirty-fifth year. In seven cases out of ten the practitioner could not make a diagnosis unless he knew the exact situation and action of the multitude of parts which made up the human body. But when we turned to our textbooks of anatomy we found that less than half of their pages were devoted to a study of the action and uses of parts. It was not, so in the early textbooks, they were keys to the living body. Textbooks now were masses of description. Our examination papers were a wearisome repetition of "describe" this and "describe" that, as if a student could apply pure description in practice, or obtain any assistance from it in the diagnosis, treatment, or prevention of disease. Here again the reform must lie with the teachers.

Professor Sir E. RUTHERFORD, F. R. C., was of the opinion that as large a proportion as possible of medical students should receive a sound training of honors standard in pure science before or during their more professional studies. The best method of dealing with the present unsatisfactory situation seemed to require a preliminary knowledge of science, and particularly of physics and chemistry, before admission as a medical student. This preliminary training could best be given in the schools, where instead of being concentrated in a brief course two years or so might be devoted to gaining a sound knowledge of some branches of physics and chemistry. The element of time was of great importance in gaining a grasp of scientific principles, and for this the present university training was much too concentrated.

Dr J. LORRAIN SMITH, professor of pathology at the University of Edinburgh, stated that in general the present curriculum was wasteful of the students' time because it gave a general introduction to the sciences but left it to the later teachers or the students themselves to apply the principles and methods of these sciences in the various branches of medicine. A continuity of teaching would concentrate the intellectual effort and would attain with much more certainty the standard of

work which the curriculum was designed to reach.

MR. ARTHUR SMITHELLS, F. R. S., professor of chemistry at the University of Leeds, criticized severely the cram system of preparing medical students for the work of medicine. He pointed out that a conventional syllabus had been created and the subject had been scheduled, with the inevitable results. The teacher was put in bonds and in one way or another, irrespective of his own views and methods, must prepare the student for the prescribed test as applied by any appointed outside person. The examination became the goal, the syllabus the beaten track, and the spirit of true study took flight. Medical students should be taught some chemistry at school, but the teachers of chemistry should be men of experience, possessing a wide outlook.

SECTION IN PATHOLOGY AND BACTERIOLOGY

The President, Professor J. LORRAIN SMITH, M. D., F. R. S.
in the Chair.

Present Position of Cancer Research.—Dr. J. A. MURRAY, in a further discussion of the subject, observed that for some investigators the conviction was gradually gaining ground that knowledge of the fundamental processes of cell life was not yet sufficiently advanced for the special purpose of cancer research. The cancer cell was in some way different from the cells of the same kind among which it originated. The nature of the change was still unknown. It was probably thoroughgoing and in most instances of a surprising degree of permanence. All the differences which had been found thus far between cancer cells and those of adult tissues could be paralleled in rapidly growing tissues of the embryo. Cancerous tissue, for example, contained more water of imbibition than adult tissue, and the most rapidly growing tumors had the highest proportion of water to solids. In consequence some slowly growing tumors were found to be less watery than testis and embryonic tissues. The differences in this respect were not absolute, so that no one could say that no cancer had less than a certain percentage of water and below this level were ranged all normal tissues, embryonic and adult.

The line of investigation which was being pursued at present was the study of normal and tumor cells by culture outside the body. Murray was of the opinion that when technical improvements had increased the flexibility of this method it should provide a powerful means of attack on the fundamental problems of the disease. At present the technical difficulties made the mere achievement of maintaining tissue cultures something of a *tour de force*. The one positive character of new growths was their progressive proliferation uninfluenced by the forces limiting the increase of the elements of healthy or diseased tissues. The transplantable tumors of laboratory animals presented this problem. The subtlety of the cellular derangement and its close contact with the fundamental problems of biology gave an atmosphere of adventure to every attempt, however indirect it might seem, which human ingenuity devised to elucidate the harmonies and contradictions which lay on every side of the problem of cancer.

THE INFLUENCE OF THE COLOR OF URINE ON READINGS OF THE PHENOL-SULPHONEPHTHALEIN TEST.*

By VICTOR COX PEDERSEN, A. M., M. D., F. A. C. S.,
New York.

The aim of this paper is to account for the fifteen per cent. apparent loss of dye, indicated by the readings of the scale, between the usual maximum of eighty-five per cent. of the material excreted by the patient in two hours and the one hundred per cent. of the phenolsulphonephtalein that has been injected. So far as a research of literature reveals, this question has never been fully studied, perhaps because the practical results have been regarded as good enough without settlement of this doubt.

I thought that much of this fifteen per cent. would be found absorbed by the color of the urine in such a way that a reliable percentage table could be evolved for the various colors of urine as given by Vogel's scale. Such tables would permit the readings to be brought to nearly an absolute total instead of as at present an indicated total with an error of about fifteen per cent. It was a great surprise, however, as shown hereinafter, to find that the darker the color of the fluid tested the higher the percentage of error in the reading.

The factor responsible is that of color alteration or combination, so that one cannot really match the beautiful reddish purple of the alkalized phenolsulphonephtalein test solution with the same quality of reddish purple in the urine, because the latter is materially altered by the urinary pigments. In fact, therefore, the test is in very large degree one of judging the intensity of two colors nearly alike but never absolutely alike in tone or quality.

The possible sources of destruction of a portion of the dye are metabolism, excretion, technic and vision. Each of these factors requires discussion.

The metabolic or physiological factors presuppose destruction of this fifteen per cent. of the dye in the liver or elsewhere in the body. Several authors suggest this explanation but literature records no experiments in support or denial of it. It is, of course, quite certain that at least some loss of this kind occurs, but the amount is probably amazingly small.

The excretory factors establish that after the second hour of the ordinary test very little of the dye is recovered. Of course if only fifteen per cent. would remain it could not be accurately read except by the author's (1) method of subdilution and computation. Several years ago I carried on a number of experiments which were never published. They tended to show that during the twenty-four hours following the test the percentage of dye was very hard to measure unless the total excretion during the first two hours was relatively low. As an average very little dye was recovered after the fourth hour of the test. If these observations were correct one may say that the entire excretion is over on an average of four hours.

The technical factors to account for the loss of the fifteen per cent. of dye are important and comprise chiefly losses during injection and deviations between measures. Elsewhere (2) I have stated: "It must be remembered that a cubic centimetre is about sixteen minims and that the loss of one drop is an error of nearly seven per cent. and two drops one of nearly fourteen per cent." Carelessness will, therefore, easily account for nearly fifteen per cent. Deviations between measures include those between the graduations of the cubic centimetre making the standard solution and those of the cubic centimetre syringe making the injection. These variations might again account for ten or fifteen per cent. As pointed out in the same paragraphs of the paper just referred to the following is important: "In order to avoid error in reading, exactly the same quantity must be used in making up the control or comparison solution, which should be accomplished by using the same syringe for measuring the fluid for the container as for the vein."

Visual factors comprise the variations in eyes from individual to individual and sometimes between the two eyes of one individual, in the perception of grades of color, absorption of color, hue of color, intensity of color and the like. As just stated the whole matter of reading the scale is the estimate of comparative intensity of slightly or greatly different colors rather than of depth of identity colors. Of course, the error in the eyes of a given observer is a constant factor of error for himself. Such error could not greatly affect clinical judgment of his cases unless more or less definite color blindness was present. For example, eyes which are five or ten per cent. above or below

*Read before the annual meeting of the American Urological Association, March 23-25, 1920.

the standard of color vision will hardly affect the interests of the patients, because all such a surgeon's reading for all his patients will contain the same five or ten per cent. of error, which thus practically eliminates itself.

It may be said that absorption error is different because all eyes, normal or otherwise, will have no escape from this error. In illustration, if that error in dark urines is an addition of ten, fifteen or twenty per cent. then a patient excreting absolutely only twenty per cent., during the first hour will be credited with readings of thirty, thirty-five or forty per cent. which are close to the normal minimum for the first hour. Again if his absolute excretion is forty per cent., then his readings will be advanced to fifty, fifty-five or sixty per cent. which again are practically the normal maximum for the first hour. Again a urine with a positive yellow like No. 3 of the Vogel scale will give much the same, although perhaps slightly lower errors. The tables of this paper, however, show that there is very little difference.

In brief, this question of color absorption in this article is somewhat analogous to the difficulties of reading small percentages except by the author's method of subdilution and computation described in the paper (2) already quoted, in these words: "Those who have done much of this work are familiar with the fact that the most convenient readings on the colorimeter are from about thirty per cent. upward, and with the fact that below thirty per cent. the colors are so pale as to make it almost impossible to read percentages within five per cent. of error, which has been accepted as the standard of accuracy. By my method of subdilution I feel that far more accurate readings may be obtained. The steps are as follows: When the quantity of dye in a specimen is obviously little, instead of raising this excretion to the dilution of 1,000 c. c., it is raised only to a prime factor of 1,000—for example, 50, 100, 200 or 250 c. c. The reading is then taken and must obviously be divided by the number of times which the prime factor of subdilution is contained in 1,000 which, following the foregoing prime factors in the order given, would make the divisors 20, 10, 5 or 4, and then if the method of subdivision had been followed this reading must be again multiplied by two to reach the correct result. A good eye for color with the aid of these procedures will make the reading almost absolutely accurate."

The question of error through color absorption or combination is in a degree academic when one considers the large amount of excellent work done with the phenolsulphonophthalein test as it stands. The matter has a practical value of even greater degree when one considers the borderline or doubtful cases in which a patient's urine may give a reading showing an indicated excretion of fifty per cent. but through its having a dark color may have an absolute excretion of only thirty per cent. Such a patient might be subjected to operation and perish because of this variation between his indicated and absolute excretion. Every urologist has had patients who died notwithstanding a seemingly favorable phenolsulphonophthalein reading. One cause may be this color absorption error in the test and subsequent judgment therefrom. The average

report does not note or respect the color of the urine. Highly pathological urine is usually largely altered in color.

It may be urged that chemical hematology of the blood for its content of urea, uric acid, creatinin, sugar, chlorides and the like is an almost infallible check on all this work. I always employ it with great satisfaction. It should never be omitted even in apparently favorable cases and is essential in all borderline cases. Unfortunately, however, much modern kidney surgery must be done away from laboratories equipped for this work. If, therefore, the detection and correction of a color absorption error will aid the surgeon who cannot reach such a laboratory quickly, much practical value should be the result. This fact again emphasizes the great practical value of this entire matter.

In the following observation caution was taken to eliminate even small errors in measuring, mixing, readings, the Heliger colorimeter and my own eyes. Each of these five matters deserves separate notice.

The measuring contained the following checks. The same litre measure was used throughout and accurately levelled. The alkali was dumped in first to avoid addition to the 1,000 c. c. of the stock or the test solution or urine. The same syringe (one c. c. capacity) graduated in tenths was used to make all stock solutions and all additions from small to high percentages. The drop was washed off the needle into the stock or test solutions, thus avoiding the approximate seven per cent. of error by its loss, previously discussed. The test cup was always dumped back into the litre graduate to avoid decrease below the 1,000 c. c. Subdilution by the author's method was not employed except in the tables where so stated, because it was thought that the average reader would prefer to have every test brought up to 1,000 c. c. These tables, as given, were really control tests. Mixing was felt to require pouring the stock and test fluid from the litre graduate into a pitcher and back three or four times. The majority of the fluids were so alkaline as to be slippery to the finger and the color unquestionably uniform.

Readings were felt to demand the following checks: A white light such as is used in microscopy was very serviceable because it did not add to the reddish or yellow color of the test fluid. The test wedge was not changed on the scale until the reading of one test was compared with the next preceding test. Thus, for example, the reading for twenty per cent. was compared with forty per cent., and forty with sixty and sixty with eighty before the wedge was changed in position to make an independent reading for the newer and higher percentage. Binocular vision was less tiresome than monocular. Very often the scale was set at the point of known strength of the test fluid, say sixty per cent., on the chance that the reading would be correct. In not one instance, however, was the reading correct, but always too low, showing that the indicated percentage was much higher than the absolute content in the fluid. Where double readings occur in the tables it means that the eyes were shut, quickly opened and a slightly different reading obtained.

As a test of my own vision the wedge of the Heliger colorimeter was filled with properly pre-

pared stock solution, well alkalized and containing a cubic centimetre of phenolsulphonephthalein. Then a thousand c. c. of well alkalized distilled water were taken. To these were added (from the same syringe as was used in making up the foregoing stock solution) phenolsulphonephthalein ascending from one tenth c. c. to one c. c. A reading of the scale was taken at each, one tenth c. c. added and all readings were found to be without error in the scale for each known quantity of dye. This test not only proved my own perception of color to be very good but established the accuracy of my colorimeter.

In the following tables of readings in the order given distilled water was used artificially colored to imitate closely numbers 4, 3, 2 and 1 of the Vogel scale. The work was begun with the dark fluids on the ground that error would be greatest in them.

Tables numbered 1 and 2 were the first made. Ordinary electric light was used, which, although not white, did not seem to change the readings greatly from those of all other tables which were made with artificial or solar white light.

The stock solution for comparison is 1,000 c. c. of distilled water, alkalized with fifteen per cent. sodium hydroxide, with the phenolsulphonephthalein added, usually one c. c. or in larger proportional amounts such as one and one tenth or one and one fifth c. c.

TABLE 1.

VOGEL'S SCALE 4		REDDISH YELLOW		
A	B	C	D	E
Stock Solution	Test Fluid	Absolute per cent.	Indicated per cent.	Indicated Error
1000 c.c. of distilled water alkalized with 15% sodium hydroxide with dye as stated below	Fraction of 1 c.c. of dye in 1000 c.c. of distilled water alkalized with 15% sodium hydroxide	Injected into test fluid	By readings of the Heliger colorimeter	
1 c.c.	0.1	10	25-30	15-20
1 c.c.	0.2	20	35-40	15-20
1 c.c.	0.3	30	45-50	15-20
1 c.c.	0.4	40	60	20
1 c.c.	0.5	50	70	20
1 c.c.	0.6	60	80	20
1 c.c.	0.7	70	90	20
1 c.c.	0.8	80	100	20
1.10 c.c.	0.9	90	110	20
1.20 c.c.	1.0	100	120	20

The error runs between fifteen and twenty per cent. and is most significant in doubtful cases in the readings between thirty and fifty per cent.

TABLE 2.

VOGEL'S SCALE 3		DARK YELLOW		
A	B	C	D	E
Stock Solution	Test Fluid	Absolute per cent.	Indicated per cent.	Indicated Error
1000 c.c. of distilled water alkalized with 15% sodium hydroxide with dye as stated below	Fraction of 1 c.c. of dye in 1000 c.c. of distilled water alkalized with 15% sodium hydroxide	Injected into test fluid	By readings of the Heliger colorimeter	
1 c.c.	0.1	10	20	10
1 c.c.	0.2	20	30	10
1 c.c.	0.3	30	40	10
1 c.c.	0.4	40	50	10
1 c.c.	0.5	50	60-62	10-12
1 c.c.	0.6	60	70	10
1 c.c.	0.7	70	78-80	8-10
1 c.c.	0.8	80	90	10
1 c.c.	0.9	90	97-100	7-10
1 c.c.	1.0	100	110	10

¹ My chemist, M. F. Schlesinger, A. B., M. Ph., informs me that he used for Vogel's scale 4 and dark colors a saturated solution of Bismarck brown and for Vogel's scale 3 and lighter colors a saturated solution of potassium bichromate. It may be well for any other observer desirous of repeating these tests to use the same dyes.

The error averages about ten per cent. Like that in Table 1 it is important in the middle of the scale for borderline cases.

The tables from 3 forward were made with white light. This fact tends to account for many double readings. Likewise when many tests are made consecutively the eyes weary and lose decision.

TABLE 3.

VOGEL'S SCALE 4		REDDISH YELLOW		
A	B	C	D	E
Stock Solution	Test Fluid	Absolute per cent.	Indicated per cent.	Indicated Error
1000 c.c. of distilled water alkalized with 15% sodium hydroxide with dye as stated below	Fraction of 1 c.c. of dye in 1000 c.c. of distilled water alkalized with 15% sodium hydroxide	Injected into test fluid	By readings of the Heliger colorimeter	
1 c.c.	0.1	10	15-20	5-10
1 c.c.	0.2	20	35-40	15-20
1 c.c.	0.4	40	55-60	15-20
1 c.c.	0.6	60	78-80	18-20
1 c.c.	0.8	80	95-100	15-20

TABLE 4.

CONTROL OF TABLE 3		METHOD OF SUBDILUTION		
A	B	C	D	E
Stock Solution	Test Fluid	Absolute per cent.	Indicated per cent.	Indicated Error
1000 c.c. of distilled water alkalized with 15% sodium hydroxide with 4 c.c. of dye	Fraction of 1 c.c. of dye in 250 c.c. of distilled water alkalized with 15% sodium hydroxide	Injected into test fluid	By readings of the Heliger colorimeter	
4 c.c.	0.1	10	15-20+	5-10
4 c.c.	0.2	20	30-40	10-20
4 c.c.	0.4	40	60+	20
4 c.c.	0.6	60	70-80	10-20
4 c.c.	0.8	80	90-100	10-20

To demonstrate the question of this paper without multiplying detail, from Table 3 forward only alternate percentages up to eighty will be used. In Tables 3 and 4 it is noticed that the error is again close to twenty per cent. in the midscale readings. The deep color of subdilution was a disadvantage and control tables with it were not tried further.

TABLE 5.

VOGEL'S SCALE 3		DARK YELLOW		
A	B	C	D	E
Stock Solution	Test Fluid	Absolute per cent.	Indicated per cent.	Indicated Error
1000 c.c. of distilled water alkalized with 15% sodium hydroxide with dye as stated below	Fraction of 1 c.c. of dye in 1000 c.c. of distilled water alkalized with 15% sodium hydroxide	Injected into test fluid	By readings of the Heliger colorimeter	
1 c.c.	0.1	10	20 ±	10 ±
1 c.c.	0.2	20	30 ±	10 ±
1 c.c.	0.4	40	50 ±	10 ±
1 c.c.	0.6	60	70 ±	10 ±
1 c.c.	0.8	80	90 ±	10 ±

As in the preceding Table 2 the error is very close to ten per cent.

TABLE 6.

VOGEL'S SCALE 2		YELLOW		
A	B	C	D	E
Stock Solution	Test Fluid	Absolute per cent.	Indicated per cent.	Indicated Error
1000 c.c. of distilled water alkalized with 15% sodium hydroxide with dye as stated below	Fraction of 1 c.c. of dye in 1000 c.c. of distilled water alkalized with 15% sodium hydroxide	Injected into test fluid	By readings of the Heliger colorimeter	
1 c.c.	0.1	10	20	10
1 c.c.	0.2	20	30	10
1 c.c.	0.4	40	50	10
1 c.c.	0.6	60	65	5
1 c.c.	0.8	80	85	5

In tables 4, 7 and 9, instead of dividing the readings by four to compensate for the subdilution 250, the stock solution was made up with four c. c. of dye and thus the scale readings were direct and not computed:

TABLE 7.
CONTROL OF TABLE 6

METHOD OF SUBDILUTION

4 c.c.	0.6	60	65-	5
4 c.c.	0.8	80	85	5

Although the foregoing results seem to show that the apparent error in readings in dark fluids is between fifteen and twenty per cent. and that in light fluids between ten and fifteen per cent. the following two systems of controls were adopted: The full strength method and the dilute method. On the full strength principle 1,000 c. c. of plain distilled water solutions were taken, injected with the phenolsulphonophthalein from one tenth c. c. to eight tenths c. c. and readings at each step taken. Necessarily these were all normal. As each step was taken from one fraction to the next, dye was injected to bring the water up to the desired Vogel's scale color as stated in the tables 10, 11, 12 and 13. A fresh supply of water was used each time and the readings taken as stated with the resulting indicated errors.

By the dilution plan the eighty per cent. strength solution was made at once just as in the foregoing procedure, and then diluted to forty, twenty and ten per cent. With each dilution sufficient dye was added to maintain the proper Vogel's scale color. As in the first tables all these measures were identical and thus variations avoided. Tables 14, 15, 16 and 17 show these tests.

1000	0.4	40	47-50+	7-10+
1000	0.2	20	30+	10+

In order to produce the colors Vogel's scale 4-3-2-1 in tables 14 to 17, inclusive, it was found that the hypodermic syringe had to be filled four times for Vogel's scale 4; three times for Vogel's scale 3; twice for Vogel's scale 2 and once for Vogel's scale one in one thousand c. c. of water. In the dilutions for eighty per cent. to forty per cent. and from forty per cent. to twenty per cent. of the phenol-sulphonephthalein, when the stock solution was again brought up to the one thousand c. c. standard, sufficient coloring matter was introduced to secure a return to the proper Vogel scale color used for the next previous strength. In this way errors in this particular were eliminated because when forty per cent. was read off the coloring matter had been restored to the standard of the eighty per cent. solution. And so with the twenty per cent. to forty per cent. solution.

The preceding tables 1 to 17, both inclusive, complete the various observations with distilled water. The following tables 18 to 23 inclusive comprise the studies applied to mixed urines and developed by exactly the same precaution and technic. All these urines were unavoidably decomposed and turbid, but in a generous sense such changes made them simulate pathological urines well. The turbidity made the readings difficult.

TABLE 18.

RÉSUMÉ

In order to correlate all the tests and to determine the average of errors from which to draw conclusions the following tables were prepared for each of the four colors used. It will be noted that these tables of averages confirm almost exactly the conclusions finally drawn by me.

AVERAGES OF ERRORS

Primary and control tests combined in the averages

TABLE 24.
VOGEL'S SCALE 4

Per cent. of phenolsulphone-phthalein	Tables of distilled water and urine							Averages
	1	3	4	10	14	18	19	
10	18	18	8	13	17			13
20	18	18	15	13	18	10		15
40	20	18	20	13	13	10	10	15±
60	20	19	15	13	10			15±
80	20	18	15	13	13	8	10	14

TABLE 25.
VOGEL'S SCALE 3

Per cent. of phenolsulphone-phthalein	Tables of distilled water and urine						Averages
	3	5	11	15	20	22	
10	10	10	18	15			13
20	10	10	13	18	16	10	13
40	10	10	13	13	10	10	11±
60	10	10	13	10	10		11±
80	10	10	13	15	9	8	11±

In Table 24, Column 1, the dye was darker than in any other. Unfortunately two lots of dye had to be employed but the differences were not great.

40	5	10	11	8	11
60	5	5	13		8-
80	5	5	8	7	6+

CONCLUSIONS

It is reasonable to draw conclusions from the foregoing studies because of the variety of tests employed, with careful checks and controls.

The first was the direct method whereby the

phenolsulphonephthalein was in exact tenths of a c. c. added to a litre of distilled water previously colored with Vogel's scale, 4, 3, 2 and 1 dye. This work is embraced in tables 1, 2, 3, 5, 6 and 8. These tests, shown in tables 4, 7 and 9, were controlled by the method of subdilution.

It again was desirable to check up the work by the direct method which consisted in injecting the phenolsulphonephthalein into distilled water and then adding the dyes to produce Vogel's Scales 4, 3, 2 and 1. These steps are shown in tables 10, 11, 12 and 13.

A still further control was introduced by the same method but starting with eighty per cent. of phenolsulphonephthalein, then diluting it with equal parts of water for forty per cent. and twenty per cent., correcting the dilution of the dye stuff by the appropriate quantity of Vogel's scale 4, 3, 2, 1. These tests are shown in tables 14, 15, 16 and 17. The urines were tested by exactly the same steps of direct methods and control methods. The details are shown in tables 18, 19, 20, 21, 22 and 23.

Allowing for differences due to variations in the dyes used and for weariness of the eyes after making many tests the résumé shown in tables 24, 25, 26 and 27 are very interesting. From these tables it is quite evident that in urines equivalent to Vogel's Scale 4 the average error is at least fifteen per cent., probably twenty per cent., with the darker urines.

With the Vogel's scale 3 the error is at least ten per cent. and in some circumstances may be nearly fifteen per cent. With Vogel's scales 2 and 1 the indicated error is about ten per cent. As previously stated the practical importance of these indicated errors is in the middle of the scale, by which are often decided doubtful cases.

I believe that in all the ordinary scale readings ten per cent. should be deducted for pale yellow, fifteen per cent. for positive yellow and twenty per cent. for urines with a reddish or orange tinge, in order to arrive at the absolute excretion, and thereafter decide in favor of or against operation.

ADDENDUM

Since the completion and reading of this paper the thought has occurred that a series of tables should be made using Cabot's method or its equivalent, namely bottles having the same quality of glass, diameter and capacity to contain both the control fluid and the artificially colored distilled water. The purpose of this last step was to eliminate any influence which the wedge shape of the test fluid in the colorimeters might have on the readings.

The details were the same as those adopted in the original paper. For the stock solution four c. c. of strong potassium hydrate solution were poured into a 1,000 c. c. beaker and brought up to full measure. Then with all preliminary precautions phenolsulphonephthalein was injected one tenth c. c. at a time ascending to one c. c. and thus creating a set of bottles for comparison beginning with ten per cent. and ending with one hundred per cent.

The test fluids Vogel's scale 4, 3, 2 and 1 were brought in the same way up to 1,000 c. c. and then one tenth, two tenths, four tenths, six tenths and eight tenths c. c. were injected, thus producing ten,

twenty, forty, sixty and eighty solutions. Bottles of the same size, thickness and quality of glass were then filled with these fluids and compared with the test bottles just described.

Absence of a sliding scale as provided in a colorimeter made it very difficult to estimate the exact color error. It may be said in general that this method supported and corroborated the other method. The tables speak for themselves.

TABLE 28.

VOGEL'S SCALE 4		REDDISH YELLOW		
A	B	C	D	E
Stock solution	Test fluid	Absolute per cent.	Indicated per cent.	Indicated error
1000 c.c. of distilled water, alkalinized with 15 per cent. sodium hydroxide with dye as stated below.	Fraction of 1 c.c. of dye in 1000 of distilled water alkalinized with 15% sodium hydroxide V. S. 4.	Injected into test fluid	By readings of the Heliger colorimeter.	
0.1	0.1	10	20	10
0.2	0.2	20	30-35	10-15
0.4	0.4	40	50-55	10-15
0.6	0.6	60	70-75	10-15
0.8	0.8	80	90-95	10-15

There may have been a little doubt in reading due to the fact that the dyes for producing the Vogel scale colors 4-3-2-1 were in these tests different from the dyes of the other series. The ten per cent. ascents in the scale of bottles also made graduation reading difficult.

0.4	0.4	40	50—	10—
0.6	0.6	60	70—	10—
0.8	0.8	80	90—	10—

There is much more thought and labor represented in this preliminary contribution than might appear to the average reader through the approved tables. If the result is the correction of doubt in those patients who perish even after a favorable phenolsulphonephthalein test the thought and the labor will have been immeasurably worth while.

45 WEST NINTH STREET.

THE UREA OUTPUT AS A PRACTICAL KIDNEY FUNCTION TEST.

BY STEPHEN H. BLODGETT, M. D.,
Boston.

In the present rather imperfect state of our knowledge regarding diseased conditions of the kidney, the information most necessary to secure, when a patient with chronic nephritis comes under our care, is: How much is the kidney damaged as regards its ability to get rid of the waste products of metabolism, and is the condition present essentially a progressive one or not? Or perhaps I would better explain my meaning by saying that we wish to know how much the damage to the kidney interferes with the permeability as regards the waste products or toxins of body metabolism which, if not passed out through the kidney, cause poisoning and ultimately death.

If in a coal-burning furnace where we use the greatest care to keep the grate free from clinkers, and with frequent shakings we can only get through a hodful of ashes in twenty-four hours, it is perfectly obvious that we must not put more coal on the fire than will produce a hodful of ashes in twenty-four hours; for if we do, the surplus ash accumulating day by day will ultimately choke the fire and put it out.

It seems to me that the knowledge that is vital, in order that we may prescribe a suitable diet and give a fairly accurate prognosis is what part of the waste products that should pass through, or be eliminated by, the healthy kidney cannot be fully eliminated by the kidney under consideration. This will give us an indication as to the amount of certain foods it is safe or advisable to allow our patient. Having procured an answer to this question, we must then limit the amount of exercise or activity to correspond to the amount of food that we find we can safely allow. To illustrate again by the furnace fire: If we find the grate is damaged, first find out how much ash we can get through the grate daily; secondly, put in only that amount of coal which, when burned, will produce that amount of ash; and, thirdly, try to heat only as much of the house as that amount of coal will heat and do not expect the furnace with a damaged grate (therefore a restriction as to the amount of ashes that can pass through) and consequently a restricted capacity, to burn coal to heat the same number of rooms that the furnace, when new, with a perfect grate would formerly heat.

First and foremost, I would say that if some foreign, innocuous substance, when injected into the body, will be eliminated by the kidney at a certain rate, it does not follow that the poisons from the waste of the body will be eliminated at the same rate. It must be understood that it depends on what part of the kidney is affected as to which of the various waste products may or may not be adequately eliminated. For instance, we are all familiar with conditions of the kidney, where the nitrogenous waste (urea) is freely passed through while, on the other hand, only very small amounts of sodium chloride are eliminated. In other cases of kidney damage, relatively small amounts of urea can pass through the kidney, while sodium chloride will pass freely; and there are other conditions where only relatively small amounts of either urea or sodium chloride will pass through.

What particular portions of the kidney are at fault when these various imperfect eliminations occur, I shall not discuss here, for this knowledge will not help us to formulate a better diet for our patient or to give a more correct prognosis; and besides this, I do not feel that the question is definitely settled as yet, but should be considered as theoretical rather than proved.

We know that the inability to properly eliminate salt by the kidney is usually an accompaniment of an acute disease, and the retention does not cause poisoning and death. On the other hand, we know that the retention of toxins which the kidney is unable to eliminate to the same degree as urea, causes a poisoning and ultimately death, if continued long enough.

It has been frequently stated by many medical writers that the amount of urea eliminated by the kidney has an absolute relation to the amount of nitrogenous food ingested. This is true, to a large extent, in health but in some conditions of pregnancy and in many conditions of a damaged kidney it is not true. Under these latter conditions the urea excreted may be much less than would be represented by the amount of nitrogenous food taken in, with a consequent retention of certain poisons in the system, and when this retention is continued long enough or in large amounts, death will ensue.

Therefore, it seems clear that in order to secure information as to the ability of the kidney to do the work which is vitally important, it is in many cases absolutely necessary to know just how much urea waste the kidney under discussion will eliminate in twenty-four hours, and not how much sodium chloride or phenolsulphonephthalein or any other substance can be eliminated unless the ability of the kidney to eliminate any of these substances is shown to be parallel to the elimination of the urea poison.

So far as we know at present, the ability of the kidney to filter out, or eliminate from the blood any known substance is not in many kidney conditions an exact measure of the kidney's ability to filter out or eliminate the urea poison. Therefore, because in most chronic kidney conditions the knowledge regarding the urea poison is the most vitally important thing for us to discover, it stands to reason that in these conditions, the ability to filter

out or eliminate some foreign substance is of little benefit to us as far as increasing our knowledge as to what is the best and safest food, also the proper amount, for our patient, and in aiding us to give a fairly accurate prognosis.

As far as my experience goes, there is at present no one of the so-called function tests that will give us the needed information in all cases of damaged kidney, and the particular cases in which tests fail are the very ones in which the information we seek through the test is vitally necessary in order that we may successfully advise our patient as to the quality and amount of diet, and as to exercise.

In order to illustrate my meaning more fully, I will quote briefly from several cases:

CASE I.—The patient had been a semiinvalid for several years, and had consulted several physicians. Two weeks before I saw her, her urine had been examined and something had been injected into her arm and her urine collected through a catheter for two hours. After this her husband had been assured that there was no serious kidney condition present, and she was allowed an unrestricted diet. One year ago she had weighed 132 pounds; now she weighs 120 pounds; was sleeping well; in fact, was rather doxy and drowsed a lot. The blood pressure was 170 systolic, 110 diastolic, pulse pressure 60. Her heart was regular, not enlarged but somewhat weak, and the patient was slightly listless. She did not have a good appetite, but had been eating meat or eggs at least twice a day, with two glasses of milk. She was placed on the following diet:

Breakfast.—Melon, cereal and cream, tea, half slice toast, little butter.
Dinner.—Soup (thin), string beans, baked potato, pear, and some grapes.
Supper.—Melon, puffed rice with cream, soup (thin), roll and butter, half an apple.

Of course the diet was varied from day to day by such substitutes as a peach for the pear, and we will call it her basic diet. She had previously been on a diet containing meat, eggs, and milk daily.

Day	Output Urine	Total Solids	Urea	Diet
1st	1597 c.c.	24.	15.	basic
2nd	1863 c.c.	23.6	13.6	basic
3rd	1800 c.c.	26.	11.6	basic
4th*	1810 c.c.	30.	13.	basic+1 egg+steak+fish
5th	1600 c.c.	22.	14.9	basic
6th	1744 c.c.	23.	14.	basic
7th	1774 c.c.	21.	11.	basic
8th	1600 c.c.	22.	11.2	basic+fish
9th	2012 c.c.	23.	14.	basic
10th**	1900 c.c.	22.	11.3	basic
11th	2050 c.c.	27.	14.	basic+2 eggs, steak, lamb
12th	2000 c.c.	28.	16.	basic
13th	2010 c.c.	27.	14.	basic
14th	2000 c.c.	26.	11.	basic
15th	1900 c.c.	25.	11.2	basic

*On this day, said she did not sleep as well as formerly, and when questioned, said she slept all right at night, but did not care to have her usual nap in her chair during the forenoon. She did not take another nap during the day until the twelfth day, when she slept an hour in her chair during the morning.

**On this day, was given injection in the thigh of phenothaline and the catheter was placed in her bladder; reaction in nine minutes.

It will be noticed that when the patient was placed on the low nitrogenous diet called her basic diet following a diet high in nitrogen, the urea output fell daily for three days. A significant symptom was the fact that after four days of this low nitrogen diet, the patient complained of not sleeping as well as usual, but on inquiry it developed that she slept as well as usual at night; but did not feel sleepy enough to have a nap in her chair during

the morning as she had done for months. On the fourth day there was added to her basic diet an egg for breakfast, a piece of steak for dinner, and some fish for supper. During this twenty-four hours she eliminated thirteen grams of urea, but during the following twenty-four hours, when she had returned to her basic diet, she eliminated fourteen and nine tenths grams of urea, and during the following twenty-four hours, while still on a basic diet, fourteen grams. It was not until the fourth twenty-four hour period after she had received the extra amounts of nitrogenous food that her urea output returned to normal, about eleven grams.

On the eighth day, in addition to her basic diet, she had fish at two meals (at supper, however, she only took a very small amount), returning the next day to her basic diet. During that twenty-four hours she only passed eleven and two tenths grams of urea, the second day fourteen grams, and the third day she had eleven and three tenths grams of urea, the normal output. On the next day, the eleventh day, she was given (in addition to her regular diet) two eggs for breakfast, a piece of steak for lunch, and a piece of roast lamb at supper. During that twenty-four hours she passed fourteen grams of urea. The twelfth day on basic diet she passed sixteen grams of urea, the thirteenth day fourteen grams, and the fourteenth day eleven grams, a normal amount, thus showing that it took three days for the system to get rid of the great excess of waste material, and that the system could not pass much over fifteen grams a day.

Following this, she was sent home and placed on the following diet:

Breakfast.—Fruit, half an egg, small amount of cereal and cream, (mostly top of bottle) weak coffee.
Lunch.—Four ounces soup (any kind), two vegetables, bread and butter as wanted, a glass of milk.
Supper.—Two vegetables, bread or cracker, cheese, baked apple or a sweet dessert.
Bedtime.—Fruit.

The analysis at various intervals follows:

	Output Urine	Total Solids	Urea
After 3 days	2050	24	12
After 6 days	1750	28	12.2
After 1 week	2000	28	12
After 1 month	1500	25	14

The patient had gained four pounds. Weight 119½ pounds. Blood pressure unchanged. Said she felt better than she had for years. It was deemed advisable to send this patient to a warm climate where she could be outdoors more than it seemed best for her to do in a New England winter, and where the added excretory action of the skin would help relieve the kidney.

While in the South, a local physician was consulted in relation to a slight diarrhea. Later he decided she did not have a damaged kidney, and advised her to go to a large hospital for observation. The patient followed the advice, and was admitted as a patient for observation. Three days later, following various tests, one of which was an injection in the arm and collecting the urine for four hours by catheter, her husband was told that her kidneys were working properly, and that she needed a much more nourishing diet in order to build her up. She was then given three eggs a day, one quarter pound of meat, and a pint of milk, besides vegetables. After six days on the new diet, she was found by the nurse one morning to

be nearly unconscious; within six hours she became comatose, and twelve hours later, died in coma (uremia?).

CASE II.—This patient, briefly gave a history that for several years he had had slight dyspnea on exertion. One year ago, there was sudden loss of sight in one eye, which gradually improved. No other symptoms except that he had lost about fifteen pounds in three months. One month ago, he had suddenly lost consciousness; no convulsions; consciousness slowly returned in about ten hours. This attack occurred following two days when the thermometer was below zero.

He came under my care with the following analysis: 2,130 c. c., slightly pale color; specific gravity, 1,009. Total solids forty-three grams. Urea twenty-one grams; very slight trace albumin; many hyaline and granular casts, numerous renal cells. Heart strong, regular; apex beat two inches outside nipple line. He was placed on a diet as follows:

Breakfast.—One half grapefruit or an orange, toast or biscuit and butter, cereal and cream with sugar.

Dinner.—Bread, any cereal, any dessert.

Supper.—Any vegetable, any vegetable or fruit salad, baked apple and cream and sugar.

Two glasses milk during twenty-four hours.

This continued for five days; on the sixth was added a dropped egg at breakfast, one glass of milk at 10 a. m. Dinner, a large portion of turkey. Supper, custard containing two eggs. Bedtime, a glass of milk; seventh day, return to previous diet; ninth day, discontinue the milk; eleventh day, diet to consist only of cereals, fruits and vegetables.

Day	Output Urine c.c.	Total Solids	Urea	Diet
1	830	25.	12.4	basic (part of this urine was lost)
2	1180	43.8	18.8	basic
3	1240	55.	16.	basic
4	1120	44.	15.6	basic
5	1660	61.	19.9	basic
6	1360	76.	23.	extra nitrogen
7	1720	64.	20.6	basic
8	1570	54.7	18.8	basic
9	1660	61.7	21.5	basic minus milk
10	1480	72.	19.2	
11			14.	only cereals, fruits and vegetables
12	1840	63.	16.	
13	950	55.	17.1	

Creatinin content of blood=.3 per 100 c.c.

On the tenth day, phenolsulphonophthalein was injected, and the catheter showed reaction in fifteen minutes. This patient apparently could pass a moderate amount of urea through the kidney, and was given a home diet as follows:

Breakfast.—Fruit, egg, bread, coffee and cream.

Dinner.—Soup (milk, corn or potato), any vegetable, bread, and a dessert containing one egg.

Supper.—Any vegetable, bread and butter, cheese, olives or baked apple.

Two weeks after leaving the hospital, analysis showed 1,892 c. c., slightly pale, acid, specific gravity 1,011, total solids 49, urea 17, albumin trace +. A few fine granular casts small amount of free fat.

About one week after this he became unconscious, with the following history. The weather had been extremely cold for several days; the patient got up as usual at 6 a. m. He ate breakfast at 7:30 and put on his overcoat and hat and went to his office at 9 (five minutes' walk). He went to his desk, and began work. Soon the janitor came in, and failing to get intelligent replies to questions, began to observe him carefully. In about ten minutes the patient arose from his chair and fell to the floor. He was taken in an ambulance to the hospital, and about four hours later would put

out his tongue when sharply ordered to do so, and in twelve hours would answer questions; in twenty-four hours he was apparently normal mentally, except that he could not remember any of the happenings. The next day, by careful questioning, he could remember having eaten breakfast before the attack, but could not recall what he had eaten, and had no recollection of anything after breakfast until he realized he was in a hospital about eight hours later. He remained in a hospital until he went to Florida, where he was getting on nicely until he had a cerebral hemorrhage, and died in twelve hours.

In this case, while the food test showed that the excretion of urea was only slightly delayed after the ingestion of nitrogenous food the phenolsulphonophthalein test showed a marked delay. It was therefore considered advisable to give the patient a sufficient amount of nitrogenous food and to allow a fair amount of exercise.

CASE III.—This patient was a woman, aged forty-six years, the menopause passed. Five years ago, felt tired most of the time, and was examined by a physician, who said she had nephritis. She has been on a restricted diet as regards meat since that time. She has slight dyspnea on exertion, and tires easily; digestion good; headaches very rare. No excess of urine at night; specific gravity low for several years. Sleeps well, but dreams a great deal. Feels tired when she awakes, but by nine o'clock feels better. Blood pressure systolic 120, diastolic 85, pulse pressure 35. Heart in good condition. Weight, 160 pounds.

Analysis of five years previously showed 1,300 c. c. pale, specific gravity 1011, urea thirteen grams, very slight trace of albumin; rare hyaline casts. Four years previously, 1,655 c. c. pale, 1006 specific gravity, urea eleven grams, very slight trace albumin. First, previous to examination, urine showed 1,400 c. c. yellow, acid, 1010 specific gravity thirty-three grams solids, nine grams urea; slightest possible trace of albumin; occasional hyaline cast. She was placed on the following diet:

Breakfast.—Toast and butter, weak coffee and cream.

Dinner.—Potatoes, string beans, or peas, or asparagus, berries and cream for dessert, water.

Supper.—Bread, any vegetable salad, any of the following vegetables: beans, peas, asparagus, beets, or squash, and any fruit.

This will be called her basic diet.

Day	Output Urine c.c.	Total Solids	Urea	Diet
1	1450	20.	11.5	basic
2	1537	28.7	12.3	basic
3	1242	29.	16.	basic + 2 eggs + 3 glasses milk, steak and 2 chops.
4	1537	43.	24.6	basic + 2 eggs + 3 glasses milk, steak and 2 chops
5	1714	41.	19.5	basic
6	1361	26.	12.	basic
7	1301	27.	12.	basic (took excessive exercise)
8	1420	33.	11.1	basic
9	780	23.	11.	basic (very hot day, 100-mile auto ride)
10	769	53.	20.	basic + 5 eggs
11	lost			lost
12	1124	26.	10.	basic
13	1242	38.	16.1	basic + 1 glass milk, 3 eggs, ¼ lb. cheese
14	1200	29.	11.4	basic

Phenolsulphonophthalein injected showed reaction in sixteen minutes; first hour, twenty-two per cent.; second hour, fifteen per cent.

In this case I wished to find out if excessive exercise or long auto rides had any deleterious effects on the kidney output. As will be seen, no such effects were apparent. From the rapidity with which the urea was eliminated after the ingestion

of an extra amount, it was felt that the patient had been on a too restricted diet, and had taken too much exercise, considering the restricted diet. She was, therefore, sent home and placed on the following diet: Basic plus an egg for breakfast; a glass of milk at 10 a. m.; an egg in dessert at dinner; considerable cheese at supper.

Two weeks later she reported; weight, 165 pounds. Was feeling better than for several years. Urine analysis, 1,892 c. c., color slightly pale, specific gravity 1009, solids 40 grams, urea 17 grams, very slight trace albumin, rare hyaline casts. Blood pressure, diastolic 120, systolic 75; pulse pressure 45. Two months later she was feeling very well, and her family reported that she had more energy than for years. The urine showed 2,012 c. c., color pale specific gravity 1009, 42 grams solids, 20 grams urea, slightest possible trace albumin, rare hyaline casts. Weight 166½ pounds. Ten months later she was compelled to undergo a considerable physical strain for two weeks, but without undue fatigue, and showed 946 c. c., color normal, specific gravity 1018, solids 40 grams, urea 21 grams, slightest possible trace of albumin. No casts.

I shall not quote from any more cases, as I feel that these typical cases are sufficient to illustrate my points. In the first, the patient showed an inability to pass more than about sixteen grams of urea daily through the kidney. The phenolsulphonophthalein test (catheter in bladder) showed a reaction in nine minutes. When placed on a diet not making more than twelve to fourteen grams of urea daily, and very limited exercise, she gained in weight and strength; but when placed by another physician on a highly nitrogenous diet for a week in order to build her up, coma developed and death followed (uremia?).

The second patient had a contracted kidney, but was able to pass ordinary amounts of urea. The phenolsulphonophthalein test showed reaction in fifteen minutes. He was allowed in his diet enough milk and eggs to have an output of fifteen to twenty grams of urea daily, and was doing well until a cerebral hemorrhage caused death.

The third patient had been on a very nitrogenous restricted diet for several years, and was very active, but easily tired. The food test showed she could pass much more nitrogenous waste (urea) than her diet contained. The phenolsulphonophthalein showed a reaction in sixteen minutes. She was given more nitrogenous food, and has been better and has felt better than for several years.

CONCLUSIONS.

The ability of the kidney to pass off the waste products of metabolism is not, in many cases, shown by any of the so-called kidney function tests.

The ability of the kidney to pass off the dangerous waste products of metabolism is easily discovered by means of feeding definite amounts of nitrogenous food to a person previously put on a so-called basic diet and watching the output of urea.

Having this knowledge, the diet can then be built up so that the person takes the maximum amount of nitrogenous food, the waste from which his kidneys can get rid of, and then his exercise must be limited to correspond to his prescribed diet.

SURGERY OF THE PROSTATE.*

By JOHN F. X. JONES, B. Sc., M. D.,
A. M., F. A. C. S.,
Philadelphia,

Instructor in Surgery in the Jefferson Medical College; Surgeon to St. Joseph's Hospital, Misericordia Hospital and St. Agnes' Hospital; Lieutenant, Medical Corps, U. S. N. R. F.

Glancing at the historical chapters of Deaver (1) and of F. S. Watson (2) one is amazed at the vicissitudes of fortune undergone by the offending prostate. It has been tunnelled, compressed, crushed, twisted, cooked, excised, enucleated, electrified and punched either *per urethram*, perineally, or suprapubically. Since it first assumed surgical importance it has created difference of opinion as to the etiology of its enlargement, the anatomy of its component parts its physiology, pathology, and the proper method of removing it.

Varied as well as numerous have been the theories regarding the pathogenesis of the enlarged prostate, hence a multiplicity of statements somewhat confusing, for instance: "All are agreed that the true hyperplasia of the gland elements is not the result of inflammation. On the other hand, it is the writer's belief that many of the deformities of the prostate where there is no true cytoplasia are the results of inflammation" (Pilcher) (3). "The evidence derived from the more recent pathological studies of the prostate gland points somewhat to the dependence of this condition upon chronic inflammation, etc." (White and Martin) (4). . . . And then these authors exhibit the arguments against the inflammation theory. Ciechanowski (5) alleges that prostatism, whether adenomatous or sclerotic, is essentially the same; that it is due to obscure, inflammatory processes originating in the stroma of the gland, etc. . . . And Keyes (5), not being in sympathy with this view, thinks that we should accept the theory that the adenomatous changes are due to a neoplastic process and that the sclerotic changes are the results of inflammation. Ramon Guiteras (6) accepted the theory of the French school that "So-called hypertrophy of the prostate is benign neoplasm."

Then there is the arteriosclerosis theory (Guyon and Launois) (7), which was apparently ousted by the theory of Casper and Motz (8). Velpeau's (9) fibromyoma and White's (10) sexual senility theories have also had their advocates. Hawley (11) believes that altered prostatic secretion is the cause of the enlargement. Even the view that prostatic hypertrophy is essentially a senile change has been opposed. (Bangs) (12). Perverted action of the testes, pelvic congestion and sexual excesses have been cited as causes, but little is known about the etiology of simple prostatic hypertrophy.

Lowsley (13) has clarified the question of the lobes of the prostate, having shown that this gland develops from five separate buds. Physiologists as yet have not agreed upon the mechanism of micturition and hence some writers maintain that the prostate is concerned in this act and others (notably Keyes) (14) assert that the prostate has nothing to do with urination.

*Read before the St. Joseph's Hospital Clinical Conference February 10, 1920.

Of the many classifications of benign enlargements of the prostate that of Pilcher (15) seems the least involved. I quote it in full: "Excluding syphilis, tuberculosis and cancerous lesions of the prostate, the noninflammatory enlargements of the prostate are either cytological or mechanical, viz: 1. Cytological hyperplasia, a, of the parenchyma, b, of the stroma, c. of both; 2, mechanical—due to retention of gland contents with cystic dilatation. In addition to this we have deformities in and about the prostate due to inflammation and irregularities of development of accessory glands which cause symptoms similar to hypertrophy of the prostate."

As to the manner of removing the prostate, it is becoming more and more apparent that the surgeon must use a method to fit the case and not try to make the case fit the method. While the suprapubic operation has given wonderful results in the hands of its masterful exponent, Freyer (16), and while the perineal method, when performed by its most able advocate, Young (17), has shown a surprisingly low mortality, yet the surgeon who limits himself to either method exclusively cannot help, sooner or later, doing an injustice to his patient. If the operation has not been selected with due regard to the position and size of the enlarged gland, incontinence of urine or rectourethral fistula may follow either method. The small fibrous gland should not be removed suprapubically; the large, soft gland which projects into the bladder ought to be removed suprapubically. If the abdomen is thick and the bladder small the perineal is the safer method. When the gland is not palpable *per rectum*, but presents symptoms and is demonstrably enlarged when seen through the cystoscope, the suprapubic is the better method. John H. Cunningham (18) believes that "Those professing to be expert in prostatic surgery should possess a skill in performing the different proved operations and should have the ability to select the most appropriate operation for the individual, not employing a single operative technic for all patients." J. Chalmers DaCosta (19) says, "No one routine plan is suitable in all cases. The patient should be studied, and the operation chosen which is safest and best for that individual patient. The surgeon who uses one method only must wrong many patients, and he retains consistency at the expense of humanity."

Young's (20) punch operation, originally recommended for obstruction of the vesical neck by medium bar (Randall) (21), sclerosis of the vesical neck and intravesical or intraurethral isolated prostatic lobules, should be limited, according to Braasch (22), "to cases in which the superficial medium tissues obstruct the vesical orifice, and to occasional cases of involvement of the bilateral lobes in which enucleation is otherwise inadvisable." According to Judd (23), it is an operation which requires considerable skill. It may be followed by bleeding and may necessitate subsequent operations.

Prostatotomy by means of the Bottini (24) or Chetwood (25) method should be employed in such aged and enfeebled subjects as can neither endure catheter life nor submit to a prostatectomy. There is an element of uncertainty about the Bottini operation, which will always retard its popularity among general surgeons who, as a class, prefer to

see what they are doing. Binnie (26) tells us that he saw one patient who had been operated upon by the Bottini method by a surgeon of great experience in this class of work, and that the patient's urethra had been burned and partly obliterated while the prostate had escaped cauterization. Bouffleur (27) performs a galvanocautery operation through a suprapubic cystotomy incision, the actual cautery having been heated to a white heat; and small median lobe enlargements of the prostate have been treated successfully through the cystoscope by means of the Oudin current.

The most important phase of the question of prostatic surgery is the proper selection of cases for operation. With the exception of the case of absolute retention which cannot be catheterized—and which may be treated by making a very small suprapubic opening into the bladder in order to allow gradual drainage through a female, selfretaining catheter (28)—there is always ample time for the careful study of cases of prostatism.

It is important, first of all, to make a diagnosis. When a patient of middle age or over complains of nocturnal irregularities of urination, one should think of hypertrophy of the prostate, urethral stricture and cancer of the prostate. While the presence or absence of stricture usually can be determined by careful investigation, it is often most difficult to separate prostatism plain from prostatism associated with carcinoma. Of course, if the carcinoma has extended beyond the limits of the gland—a hopeless state in which diagnosis is too late to be of much service—a rectal examination will reveal the growth. Small nodes in the prostate may mean tuberculosis, cancer or chronic prostatitis—or, if in the lateral lobes, perhaps stone. In such cases x ray examinations should be made, or it may be helpful to introduce a sound into the urethra during rectal palpation. It may be impossible to use either sound or cystoscope, and the latter may give no information, even when employed in such cases. If, with symptoms of prostatism, there are sciatica, pelvic pain or tumor of bone or in the abdomen, cancer of the prostate may be suspected (29). Bleeding is more frequent in simple hypertrophy than in carcinoma. Growths within the bladder may be differentiated by cystoscopic examination. Besides rectal touch, the abdomen should be palpated, the urine examined, the residual urine estimated and the length of the urethra measured. The passage of a catheter should be extremely gentle and guarded by rigid local antiseptics and the administration of hexamethylenamine—and in spite of all of these precautions, if infection does not already exist, it will usually follow the regular employment of the catheter. The cystoscope, if the urethra will tolerate its passage, will reveal stone and often afford information as to the shape and size of the prostate.

In these cases it is essential to possess information about the functional capacity of the kidneys, and, of the various tests devised for this purpose, the indigo carmin and the phenolsulphonaphthalein methods are perhaps the most practical. The indigo carmin method was introduced by Voelcker (30) and Joseph and is used in this country extensively by B. A. Thomas (31). Ira Remsen (32) was the first to make phenolsulphonaphthalein

and Rowntree and Geraghty (33) introduced this method of testing for the functional capacity of the kidneys. Of the experimental polyuria test of Albarran (34), Keyes (35) states that "its accuracy by no means compensates for the length of time consumed."

A twenty-four hours' specimen of urine should be collected. If the total quantity is between 1000 c.c. and 2000 c.c., it may be considered for all practical purposes a normal output. Oliguria and polyuria are significant of so many conditions, surgical or otherwise, that either symptom is only important when accompanied by other pathognomonic signs.

Oliguria may occur when there has been a lessening of intake of water, the intake in a water balance being water taken in as such, the watery contents of foods (vegetables, milk, etc.) and oxidation water from the oxidation of the hydrogen of fats, carbohydrates and proteins during metabolism (Barber) (36). Oliguria may be due to excessive perspiration, constant vomiting, or severe diarrhea (cholera, exophthalmic goitre). It may be the result of passive congestion of the kidney, the result of myocardial insufficiency. It may follow pressure on the renal veins by tumors or collections of fluid in the abdomen. Oliguria may be observed during the formation of edema and transudates. It may be caused by spasm of the renal arteries or arterioles as a result of acute strychnine poisoning. It occurs in gout, fevers, acute nephritis and in chronic parenchymatous nephritis. If oliguria occurs in chronic interstitial nephritis it is a danger signal of oncoming uremia. If it is accompanied by cylindruria, albumin and blood, it is a sign of organic renal disease—usually glomerulonephritis. Oliguria may mean serious impairment of kidney function, acute Bright's disease or obstruction to the outflow of the urine.

Polyuria may be due to increased circulation through the kidneys, to a watery composition of the blood or to an increase in the secretory activity of the kidney following the consumption of large quantities of liquid. Polyuria may follow the restoration of compensation in cardiac failure or in renal incompetency. It may appear during convalescence from typhoid and other fevers and while edemas and exudates are disappearing. It may be due to certain salts or drugs (sodium chloride, the caffeine group, digitalis, etc.). Polyuria may exist when there are lesions of the central nervous system, when there is injury to the floor of the fourth ventricle, in puncture of the medulla and when there is tumor anywhere in the brain. Polyuria is present in hypopituitarism and follows section of the splanchnic nerves. Cushing (37) has shown that subcortical transplantation of the posterior lobe of the hypophysis may cause polyuria. A polyuria which persists with urine of low specific gravity usually means contracted kidney or diabetes insipidus; if associated with high specific gravity we should think of diabetes mellitus. Polyuria occurs in amyloid disease of the kidney and in pyelitis. There may be a transitory (vasomotor) polyuria in migraine, epilepsy or hysteria. Polyuria occurs when there is chronic renal congestion, as in stone, prostatism, tuberculosis and retention. From all of

which it might be concluded that either oliguria or polyuria means nothing as an isolated symptom.

The specific gravity of the urine should be carefully noted in these cases of enlarged prostate. Deaver (38) states that he will not operate if the specific gravity of the urine continues below 1005.

The urea of the twenty four hours' specimen should be investigated because while absence of urea concentration in the urine does not of itself prove that there is a diseased kidney, the presence of such concentration is a sign of a healthy kidney.

A determination of the amount of nonprotein nitrogen in the blood should be made but it is of little value, as Frank (39) states, unless one is aware of the nitrogen intake. In his most interesting paper, Frank calls attention to the advent of an era of physiological surgeons the advance guard of whom have been the investigators of such vital questions as shock, acidosis and renal function. He feels, as do many others, that some of the physiological studies, which in the past have been applied to urology almost exclusively, should now take a prominent place in general operative surgery. All of Frank's conclusions are not established or beyond debate but they constitute a step in the right direction—the reduction of operative mortality—and they should be accepted or rejected after careful trial. The prostatic patient's genitourinary tract should be submitted to careful x ray examination in which it may or may not be necessary to catheterize the ureters.

In the differential diagnosis of prostatic conditions perhaps nothing is more puzzling than when the surgeon examines a sufferer from retention of urine with no palpable enlargement of his gland and with no stricture. In such a case the patient may have carcinoma and perhaps have nodules or an indurated posterior lobe; he may have a pedunculated middle lobe or bar which will show through the cystoscope; or the bladder may be paralyzed. If the bladder is paralyzed cystoscopic and urethroscopic examination may show typical trabeculation and perhaps some relaxation of the sphincters; rectal examination will be either negative or reveal a prostate which seems smaller than normal and is surrounded by flabby tissues (40); the cerebrospinal fluid will probably be positive to the Wassermann test; and perhaps there will be lessening or absence of deep muscular sensation. Judd and Braasch (40) state that in these tabetics "when it is evident that the sphincter itself is not relaxed, [and this may be noted through the cystoscope, J. F. X. J.] that there is sufficient hypertrophy of the prostate to account for the urinary obstruction, and that the general condition is favorable, then prostatectomy may be attempted." Young (41) has also operated under similar circumstances. Keyes (42) is not hopeful about operative cures in these conditions.

Rarely, fortunately, there is a condition, encountered in younger men, which is negative to rectal and cystoscopic examination and yet in which there is prostatic sclerosis. Tabes must be carefully excluded before making such a diagnosis (43). Judd (44) "believes that many of the patients with prostatic trouble, who continue to have the so-called cystitis and residual urine after the obstruction has

been removed, are in reality suffering from diverticula, and that if a careful examination is made for a diverticulum at the time of the prostatectomy in such cases this error will be avoided."

It is somewhat trite, perhaps, to say that a general and thorough physical examination should be made in addition to the urological investigations. If the surgeon can no longer trust his ear as far as hearts and lungs are concerned—which is often the case—his colleague, the internist, should be called in to permit the patient to benefit by such consultation. No prostatic (nor any other surgical case, except an emergency) should be given a general anesthesia while he has bronchitis. It is seldom, if ever, necessary to submit a case of prostatism to operation during an epidemic of influenza or of any other infectious disease. Low kidney function, heart disease with failing or absent compensation, high blood pressure, arteriosclerosis, infection anywhere in the genitourinary system, are some of the conditions which may absolutely contraindicate operation and they all will require the most careful preoperative treatment—even should operation be decided upon. We ought to be on the watch for acidosis always.

Acting on the acknowledged fact that prostatic patients, who have cystitis and other evidence of chronic infection at the time of operation, usually fare better than those who have no symptoms of infection, Judd (45) tried the use of a colon bacillus in order to modify infection in prostatectomies. His results were suggestive only but the idea should be acted upon and worked out on a large scale before drawing any conclusions. Cultures of the urine should be made in all cases of prostatism.

Preoperative drainage of the bladder ought to be effected—through the urethra, if this is possible, otherwise suprapubically—until the patient's local and general conditions warrant prostatectomy. Preliminary suprapubic drainage adds to the difficulty of the subsequent prostatectomy and, if the urethra permits of it, preoperative drainage should be conducted through the urethra. Fréyer (46) was obliged to perform the two stage operation seventy-two times only in a total of 1,550 suprapubic prostatectomies. He believes that preliminary suprapubic drainage should be effected in those cases where the bladder is badly infected, perhaps containing phosphatic stones and especially if the kidneys are involved as manifested by chills and fever, emaciation and debility and when the patient has very frequent, painless urination due to an overdistended bladder—no catheter having previously been used—and with this condition, incipient signs of uremia. In the latter case Freyer drains the bladder slowly by means of a retained catheter and a few days later does a suprapubic cystostomy. Then, in about two weeks, when the kidneys have regained normal function, he enucleates the prostate. Freyer says that it is much more difficult to remove the prostate ten days or longer after preliminary cystostomy because of increased rigidity of the tissues about the incision. Judd (23) believes that it is difficult to do an accurate operation after the bladder has been opened and drained, and a sinus has persisted for some time and that if this preliminary opening be enlarged the adjoining tissues are immediately exposed to infection. Deaver (47) thinks that it is

dangerous to enlarge the incision of a preliminary suprapubic cystostomy because of the risk of opening into the peritoneal cavity, the peritoneum having become attached to the bladder wall in the line of the original incision.

If the retained catheter is employed during the preoperative treatment of prostatism, it must be remembered that there is a well established nervous relation between the deep urethra and the secretory apparatus of the kidney (Pilcher) (48), and that anuria may result directly from the irritation of the deep urethra by the catheter. Here, obviously, the preoperative drainage must be suprapubic.

In addition to the drainage tube in the bladder, after suprapubic prostatectomy, a cigarette drain should be placed in the prevesical space—indeed, Judd's (23) suggestion to use Dakin's solution and Carrel technic in the space of Retzius seems a sound one. The same surgeon (23) does not believe in irrigation until after the first day following operation. Irrigation immediately after suprapubic prostatectomy prolongs oozing. Rockey (49) thinks that irrigation after prostatectomy is a surgical error. "It promotes the continuance of bleeding, devitalizes the freshly exposed tissues, and favors the formation of sloughs by removing the blood which is the natural hemostatic and protective of the wound."

The mortality of prostatectomy in the hands of the average general surgeon has been in the neighborhood of fifty per cent. The reduction of this mortality will depend upon:

1. Intimate association of the internist, physiologist and the laboratory man with the surgeon in the study of the case.
2. Thorough examination of the patient by one skilled in physical diagnosis—particular stress being laid upon the lungs, heart, arteries, kidneys and nervous system.
3. Complete investigation of the blood and urine by a competent laboratory man. If it gives the slightest promise of reducing the death rate, no test, functional or otherwise, should be considered by the surgeon too fantastic to merit trial.
4. Willingness and ability on the part of the surgeon to adapt his methods to the special requirements of each case—irrespective of the fact that he has rejoiced in the performance of a certain technic heretofore.

THE TREATMENT OF SPECIFIC URETHRITIS.

A Simple Technic.

BY ROBERT H. McNAIR, M. D.,
Springfield, Mass.

Almost every practitioner, whether specialist in urology or not, is doubtless aware of the fact that nitrate of silver comes nearest to being a specific against the gonococci than any other agent employed. Yet after much experimentation with various strengths of silver solution, I have come to the conclusion that the secret of a successful treatment of gonorrheal infection, especially during the first few weeks of its course, is to be found in determining the right strength of solution to apply in individual cases. In other words, it is very essential to find out definitely the strength of solution which may be safely used without inducing harmful reactionary irritation to the delicate mucous membrane already injured, and causing a greater degree of epithelial exfoliation, hence rendering the inflammatory area more favorable for the micro-organism to flourish and continue active destruction.

It is impossible to inundate completely and destroy the active germs with one free irrigation, therefore the application of the remedy must be repeated often and carefully.

I think the simple technic that has been repeatedly and quite successfully employed may be best described by citing a few typical cases of gonorrheal urethritis. Several of the patients complained of having suffered from painful nocturnal erection and troublesome chordee.

CASE I.—T. P. C., aged twenty-eight, a railroad employee, was first seen early in March of the present year, with a history of nearly five weeks' duration of free discharge and much discomfort. The patient had consulted several physicians and as many druggists. This case was one of troublesome chordee. The treatment was instituted with one half of one per cent. silver nitrate solution, after the urethra had been carefully flushed with a sterilized irrigating fluid. Thus the silver solution was gently and carefully instilled into the urethra—rather than injected by means of a properly shaped pipette.

The rubber bulb at the base of the glass instillator was quite strong enough to deliver the solution. The long, tapering neck, or nozzle, of the instillator was almost as long as an average index finger, with a smoothly turned end, so that there could be no possible danger of injury to the inflamed mucous membrane. The solution is simply sucked up into the pipette, gently inserted to the full length of the nozzle into the urethra, and the contents delivered. Several syringefuls, are used at each sitting.

This patient received just fourteen treatments, in as many consecutive days, during which period the strength of solution was gradually increased up to one and a half per cent. At the expiration of the period of daily application, the discharge had disappeared, and within a few days more there were no clap strings in the urine. After repeated tests

the patient was discharged and has remained so. Several more railroad employees subsequently came to me and were good patients.

CASE II.—On April 10, 1920, J. G., twenty-two years of age, employed by a furniture company, was referred to me for treatment. There was a free gonorrheal discharge with accompanying symptoms of the infection, subacute in character. Painful erections and chordee were complained of. This patient had also received treatment with astringent injections and capsules internally. Practically the same course of treatment was pursued, only the silver strength was increased to two per cent. solution. The discharge subsided in two weeks. Clap strings disappeared from the urine within the following week and the patient was discharged cured in just three weeks from the date of first treatment.

CASE III.—J. G. B., twenty-five years of age, a grocery clerk. History given was of a free discharge, considerable pain and swelling, that had lasted a little less than three weeks. Treatment at drug stores had been by capsules only. The patient was treated each evening, beginning with half of one per cent. silver solution, and gradually increasing the strength to two per cent.

It may be appropriate to remark here that the increase of the strength of the solution was determined by the degree of after irritation caused by the application. It has been found that in most cases the urethra will rapidly become quite tolerant to the irritating effect of silver if it is applied in gradually increasing strength and in a small quantity at a time.

The discharge had completely disappeared in this latter case after two and a half weeks of daily treatment. The two glass urine test was made for clap strings during one more week and the patient was discharged cured; there has been no further trouble. Other similar cases might be cited, but would only repeat what has been said, hence consume time and space unnecessarily. Silver properly applied is the remedy *par excellence* for specific urethritis.

THE CLINICAL STATUS OF GONORRHEA.

By JOSEPH M. CADWALLADER, A. M., M. D.,

AND

ALEXANDER A. BROWN, M. D.,

Formerly Chief of Genitourinary Service, Fort Sam Houston
Base Hospital,
San Antonio, Tex.

Having reflected upon the respectable antiquity of gonorrhea, and the voluminous mass of literature extant thereupon, one might wonder what could remain to be said upon this commonplace subject. Nevertheless, gonorrheal infection still remains a glaring social evil; not because the treatment is unsatisfactory, but because many cases are unsatisfactorily treated. In attestation of this, witness the ever large number of cases of lingering, but nevertheless curable, infection; the serious complications, usually preventable, genital, extragenital, and metastatic; the countless sufferers from pyosalpinx who flock to the gynecologist. What, then, is the reason for these grave and distressing conse-

quences? In answer to this query, we repeat our assertion: It is not because the treatment is unsatisfactory but because many cases are unsatisfactorily treated. And there are various reasons for this.

First and foremost, there still exist a not inconsiderable number of practitioners who, through superficiality or prejudice, adhere to the absurd dictum of Noeggerath: "Once a gonorrheic, always a gonorrheic; once infected, always infectious." Again there are others, and their number is not small, who, from inherent aversion, will not themselves treat such cases conscientiously, possibly not at all, and do not encourage the patients to seek proper treatment at the hands of those who are willing and competent; and still others who fail to estimate the extent and gravity of the infection, and consequently apply inadequate and improper treatment. What, therefore, is to be said and done?

Gonorrhea is a perfectly and permanently curable disease. What are the essentials to the attainment of this end? We believe that the answer may be tersely stated in three words, spirit, ability, equipment. Without an adequate armamentarium and the ability to employ it, and without conscientious effort and painstaking care in diagnosis, prognosis, and treatment, the prospect of failure is almost certain to supplant that of cure.

The prime essential is a correct and complete diagnosis: the mere fact that the patient has urethritis of gonorrheal origin is not sufficient. While always beginning in the anterior urethra, in only twenty per cent. of the cases does the infection remain limited to this part; in other words, eight out of ten patients eventually suffer from involvement of the deep urethra and the structures appertaining thereto. The extent of this involvement must always be determined; systematic examination must be made to disclose the existence of posterior urethritis, alone or in conjunction with trigonitis, prostatitis, and seminal vesiculitis. Only by this means is the practitioner able to institute intelligent treatment.

The next essential is the armamentarium: despite the triviality with which some physicians regard gonorrheal infection, we reiterate that this disease should be treated only by competent practitioners adequately equipped. Besides the commonplace instruments, the armamentarium must comprise the deep urethral instillator, endoscopes, straight and curved, with a range in calibre from twenty-two to twenty-six; cystourethroscopes and urethroscopic syringes; and finally, as the third essential, a thorough knowledge of how to use them, and a conscientious spirit in their application.

When shall the patient with gonorrhea be pronounced cured? When may he be assured of conjugal safety? Upon the answer of this weighty question may depend the future of a home; likewise the reputation of the urologist. We daily meet with extreme views: one asserting the patient to be innocuous as soon as the discharge is reduced to the so-called morning drop; the other (which is, to say the least, a blatant anachronism) that infection is never cured; that it may, phoenixlike, apparently die, and slumber in its own ashes, only to begin

life afresh five, ten or twenty years after. Both these views are illogical; both must be avoided. The patient is either infective or innocuous; which, can and must be determined. If infective he can be cured and must be treated; if free from infection he must not be denied connubial privilege. Before being pronounced clean, his condition must qualify according to a criterion embracing the following principles:

All specimens of urine obtained in the three glass test must be clear; three smears made from the affluent of the entire urethra and its appendages, and taken on alternate days must be negative; endoscopic examination must be negative as to granulations and verumontanitis; prostate and seminal vesicles must be normal to the touch and the urethra practically normal in calibre. Patients who successfully pass the foregoing tests are cured, and it is our practice to place them on probation for a period of six weeks, at the end of which time, if the urine has remained clear and sparkling, no further test examinations are required, and the patients are formally pronounced cured and permitted to marry.

If the method delineated in the foregoing is adhered to with conscientious and painstaking attention to details the practitioner need never fear for the propriety of his prognosis or the safety of his reputation. It has been our pleasurable experience to follow many of these patients to the point of begetting offspring and in not even a single instance has there been an ill consequence, which, needless to say, would have been quickly brought home had it occurred.

219 MOORE BUILDING.

"WHEN IS GONORRHEA CURED?"

BY MAURICE MELTZER, M. D.,
New York,

The question, "When is gonorrhoea cured?" is always timely, interesting and exceedingly important. For as long as human nature remains as it is, with all the teaching of sex hygiene, prophylactic instruction and an attempt to divert the minds of men by athletics and various other healthy means of recreation, gonorrhoea will probably always be with us. That gonorrhoea is a serious and obstinate disease to treat will not be denied by anyone who sees many cases and attempts to cure them. While the number of freshly infected patients in the clinic or at the office of the specialist is always numerous, how much more numerous are the chronic or so-called gleet cases. The complaints of patients in the latter instances date back from a few months to several years, in many instances despite more or less faithful adherence to treatment and the usual gonorrhoeal precautions. Either through neglect or ill-directed treatment, patients go about for months or years with symptoms of chronic gonorrhoea or recurrences, and if ignorant or depraved they are a distinct menace in the spread of the infection.

Authorities differ as to statistics, because even in the best regulated city health departments, where physicians are required to report venereal diseases,

many cases, for various reasons, are not reported. At best a statistical study can only be a relative estimate. It is safe to assume that there are more cases of venereal disease than is apparent from a glance at tables of statistics compiled by different men.

Admitting the importance of the medical side of the question, we also have to deal with the economic, sociological and moral issues; a discussion of the subject would never be complete without them. The decent, self-respecting man, who unfortunately had an attack of gonorrhoea is obsessed, and properly so, with the fear of marrying and infecting a virtuous girl. This point is emphasized by Abraham Flexner in his report on prostitution in Europe—"It is shocking to learn that almost one third of the reported cases of gonorrhoea occurred in married women to whom infection had been carried by their husbands." It is too well known that so many gynecological operations are necessary through the ignorance or wantonness of an uncured husband who infects his wife.

An uncured or chronic patient with gonorrhoea has dormant foci of infection in various parts of the urethral canal, prostate or seminal vesicles, which account for much ill health and invalidism. A persistent discharge, inconveniencing and distressing urinary symptoms due to strictures, or inflammation of the posterior urethra, prostate or seminal vesicles, arthritic or muscular pains due to toxins given off by the gonococci—all contribute to undermine health and morale. It is difficult to calculate the number of working days lost, as a direct result of severe acute symptoms, gonorrhoeal rheumatism, or operations for the relief of various complications. Gonorrhoea is considered a serious disease; in fact some regard it on a par with syphilis. Simple acute anterior urethritis, even under the best circumstances, frequently extends and complications set in due to the anatomical arrangement of the genito-urinary tract. It hardly needs further elaboration to convince one of the importance of following out a systematic plan to determine whether a patient is cured of his infection. The following examinations are essential in determining a cure.

MICROSCOPIC EXAMINATION.

In making a microscopic examination of any discharge presenting at the meatus or of that which can be expressed along the course of the urethra the discharge is gathered on a glass slide, and is fixed and stained with methylene blue solution in the usual way. The slide is then examined for the presence of pus cells, epithelia and bacteria. Special search is made for the intracellular diplococci. In chronic or subacute cases, gonococci are seldom found. One can usually distinguish a chronic discharge by the scattered fields of pus cells, epithelia, thin strands of desquamating tissue and the presence of specific or nonspecific cocci. A similar examination is made of morning drop secretions. When in doubt about the type of bacteria, a gram negative stain is made. Normally there should be no secretion and if any material is stained, it should not show any pus. Cases with redundant prepuce often show a variety of bacteria, due to balanoposthitis.

The morning drop complaint should not be dis-

missed lightly; patients are at times told to disregard it, as it is only "an escape of spermatozoa or spermatic fluid." It should always be examined microscopically and as long as pus cells are seen, there is a focus somewhere and it must be eradicated. The presence of intracellular diplococci in such smears is the exception, rather than the rule.

THE TWO GLASS TEST.

The patient is asked to void separately into two glasses, and the urine is held up before a light to note whether it is clear, cloudy, hazy or cloudy and sanguineous. The terms cloudy and hazy are arbitrarily used to denote the degree of pus in the urine, the former indicating a large amount of pus. If cloudy or hazy a small amount of thirty-three per cent. acetic acid, is added; if the urine remains cloudy or hazy then it is usually due to pus; if it clears on the addition of acetic acid, phosphates are the cause of the turbidity. In exceptional cases when the urine does not become clear, it may be due to marked desquamation of epithelia; this can be differentiated by microscopic examination. For practical purposes the urine in the first glass is taken to represent the washings of the anterior urethra and the second glass that of the posterior urethra. Theoretically this is incorrect. For the sake of analogy, the bladder is a tank which empties through a pipe, the urethra, which is divided into the proximal or posterior and distal or anterior urethra. The urine in the first glass really is that from both the posterior and anterior urethra, for coming from the bladder it washes away the secretions of the entire urethra. Therefore some urologists have adopted a five or seven glass test, which aims to examine separately the urine or washings with the secretions from the anterior and posterior urethra and from the prostate and seminal vesicles. Practically, the two glass test serves its purpose well, when it is carried out in conjunction with a systematic routine examination.

The number, size and general appearance of the shreds in a clear or cloudy urine, are noted; if the urine is perfectly clear these shreds are often examined microscopically for the presence of gonococci. The urine from a cured patient should show clear and contain few shreds; such shreds merely represent shedding from an old noninfective desquamating surface.

EXAMINATION OF THE URETHRA FOR STRICTURE.

Silk rubber *bougie-a-boules* and sounds are used for this purpose. The largest size *bougie-a-boule* or sound to pass the meatus is tried first. It is interesting to note that many individuals present meati that do not admit anything much larger than French number 20; this in itself in some cases may interfere with the proper drainage of urethral secretions. In such cases a meatotomy up to number 30 French is indicated. The bougie is gently passed down to the bulbomembranous junction (the site of the external urinary sphincter and the anterior layer of the triangular ligament.) It is then gently withdrawn. If there is any narrowing of the urethral calibre, or if there are any chronic inflammatory bands or ridges along the course of the urethra, these are felt to catch on the neck of the olivary tip of the bougie. Often several such tugs are felt

over indurated ridges, giving the sensation of a cobble stone surface. In soft or freshly forming strictures, the passage of such a soft elastic instrument often produces some bleeding. The size of a stricture, if present, is noted by the size of the bougie which it will allow to pass. The largest sized sound to pass the meatus is then gently passed through the entire urethra and into the bladder; the sound is now withdrawn. Normally, a sound passes in and out of the urethra by its own weight. A stricture, or one that is forming, grasps the sound as if between the jaws of a vise. This grasping sensation is quite characteristic of stricture formation. If, in spite of gentle technic, bleeding occurs, it is usually pathognomonic of a soft or freshly forming stricture.

EXAMINATION OF THE PROSTATE AND SEMINAL VESICLES.

It is advisable to first fill the bladder with a solution of boric acid or weak silver nitrate solution, for a distended bladder allows for a better examination of the prostate and seminal vesicles, which are brought down closer to the examining finger in the rectum. By a gentle sweeping of the finger, the size, consistency, tenderness and the presence of fibrous adhesions are noted; often one lobe is larger than the other and firm nodules may be present in one or both lobes. The vesicles in some cases are sausage shaped. The prostate and vesicles are gently, yet firmly rubbed from above downward, not laterally. The secretion expressed is caught on a glass slide and is either examined in the wet state or dried, fixed and stained with methylene blue. A search is made for pus and bacteria. The importance of this examination is to note the presence and the amount of pus cells. This examination should be repeated several times in the course of a few weeks. The number of pus cells, as a matter of convenience and routine, can be indicated by the use of plus signs. Four plus would indicate that practically every field examined shows an abundance of pus cells such as is seen in an ordinary urethral smear. Fewer pus cells are indicated by two or one plus; or, the examiner can use the terms small, moderate or large amount of pus. It is the exception rather than the rule to find intracellular diplococci in such smears. As other organisms can induce prostatitis, such secretion obtained by massage is often cultured for the identification of the organisms. Repeated smears should show no pus or but few very scattered fields in a cured case.

CYSTOURETHROSCOPIC EXAMINATION.

This examination is a visualization of the entire urethra from the bladder neck down to the meatus. The irrigating instruments of the McCarthy, Buerger or Greenberg types are ideal for this examination. They give splendid illumination and magnification; perfect detail of the mucosa is obtained. The irrigating fluid washes away bleeding surfaces or shreds. In the fluid medium, pus appears as rice flakes. One doing such examinations cannot but be impressed with the variety of lesions met in the urethra. In spite of clear urine and in some cases without any symptoms such lesions can remain undetected and can keep up the infection for

years and act as foci. The lesions encountered in the posterior urethra are: Uniform turgescence, so that the mucosa bleeds easily (soft infiltrations); erosions, granulations, or desquamations; congestion or enlargement of the verumontanum or polyps or vegetations or cystic conditions on or about the verumontanum. In the anterior urethra: Soft infiltrations, hard infiltrations (characterized by special paleness of the mucosa which later on becomes a yellowish white, or the urethra appears inelastic and is actually the seat of true stricture formation); on the roof and lateral walls the glands of Littre and the crypts of Morgagni are bright red in appearance and are the seat of subacute or chronic inflammation; erosions and desquamating surfaces are often seen on the floor. Cystourethroscopy is therefore a very important examination in that it calls attention to lesions that may never be suspected, and in that appropriate treatment can be instituted to cure them. It is most gratifying to the examiner to note by subsequent examinations the improvement or cure of such lesions after a rational method of treatment.

COMPLEMENT FIXATION TEST OF THE BLOOD.

This is a serological test similar to and based on the same principle as the Wassermann test for syphilis, and like the Wassermann test it is only of value in conjunction with clinical findings. A positive complement fixation test without symptoms should institute a quest for foci. On the other hand, numerous patients are seen with symptoms and objective evidence of chronic gonorrhea who give a negative test. Obviously a negative test in such cases is of no value. In acute cases, in discharging patients as cured it should be remembered that the complement fixation test should be done about two to three months after the infection has presumably been cured. On the other hand, if the blood is positive and all the other examinations show no evidence of infection, then this positive test should carry no more weight than a positive Wassermann test without any clinical or laboratory manifestations of syphilis. A positive test helps in the diagnosis of rheumatic joints.

CULTURAL METHODS FOR THE ISOLATION OF THE GONOCOCCI.

Usually the methylene blue and gram negative stains are sufficient for the identification of the gonococcus. In chronic cases where the bacteriological examinations show a variety of bacteria in smears, to establish definitely a diagnosis of gonorrhea, the secretions from the genitourinary tract should be cultured. The secretions must be grown on suitable culture media. In a paper of this kind the technical laboratory details are omitted; these are lucidly explained in standard bacteriological works. In the male the secretions from the urethra, bladder, prostate and seminal vesicles and in the female those of the urethra, bladder, cervix and vagina are utilized. This method is of great importance in differential diagnosis of inflammation in the female and often offers the only absolute way of deciding whether the gonococcus is the etiological factor. This method should be utilized when repeated smear examinations show pus but no bacteria.

COMMENT.

Gonorrhoea can be cured. In acute cases a cure may even require three months or longer. In chronic cases a much longer time is required, depending on the objective findings in the individual case. The old antiquated method of suggesting a sexual or alcoholic spree, to see whether a urethral discharge is noted thereafter, should be condemned because it is unreliable and unscientific. Likewise the examination of a condom specimen for the presence of gonococci is not enough. Too often laboratory reports of centrifuged urines or prostatic and seminal vesicle smears simply state that no gonococci are found, but with no mention of the presence or the amount of pus, which is an indicator of a focus. It is only by a systematic routine examination that one can tell whether a patient is free from infection. What is still more important foci or lesions are so often discovered that would have gone on unnoticed.

1. A cured patient should present no morning drop or urethral secretion at any time of the day.
2. Microscopical examination should show no pus or gonococci in the urine, prostatic, or seminal vesicle smears.
3. The urine should be clear, though in some cases small noninfective desquamating shreds may persist.
4. The urethral lumen should be free from any narrowing or stricture formation.
5. The complement fixation test should be negative in conjunction with the other findings.
6. In doubtful cases the secretions from the genitourinary organs should be cultured to prove the absence of gonococci on suitable culture media.
7. Cystourethroscopic examination should show the urethra free of lesions.

115 WEST SIXTEENTH STREET.

THE INTENSIVE ADMINISTRATION OF ARSPHENAMINE.

BY HERMAN GOODMAN, B. S., M. D.,
New York.

Since the publication of the reports (1) of the treatment of women with arsenobenzol and neodiarsenol requests for the result of this form of therapy in men have been received.

The following serves as a report of the intensive specific therapy in eighty hospitalized syphilitic negro patients. The cases were divided among the syphilitic periods as follows:

Primary syphilis, twenty-eight cases; silent generalization, twenty-three cases; secondary syphilis, sixteen cases; latent tertiary, four cases; active tertiary, nine cases. Diagnosis in primary cases was made by the demonstration of the spirochæta pallida in cases where the diagnosis was at all doubtful clinically (2).

We regarded the history as of little value. The stated incubation time cannot be reliable with men who are repeatedly exposing themselves to infection. Even the duration given by the patient was more often than not at variance with the known course of the disease. Men told us, with no intent to deceive, that the lesion on the penis had been there

only two or three days, yet the inguinal nodes were enlarged and the Wassermann test was reported four plus positive.

As often demonstrated before, the frenum is a point of lowered resistance to the entry of the spirochæta pallida, and at least half of our patients presented the initial lesion in this location. In not a few of these cases, neglect and secondary infection leading to ulceration had proceeded to such an extent that the corpora cavernosa and corpus spongiosum were exposed for over an inch. In our opinion practically every lesion at the frenum harbors the spirochæta pallida.

We rarely saw the indurated, ulcerated papular chancre which bears Hunter's name. The ulcerated lesions we did see were usually larger and the tumor character was absent. One type of initial lesion was presented by multiple lesions of the free edge of the prepuce, a sort of rosette, which, because of the accompanying edema, resulted in an artificial phimosis. Another fairly common type of initial lesion was one of the meatus urinarius. The sclerosis was situated either on the mucous surface or on the skin border.

Patients were admitted with the clinical diagnosis of primary syphilis who had passed the primary serological stage and were in the stage of silent generalization. These patients presented chancres, no secondary lesions of the skin or mucous membranes but the Wassermann tests were reported positive four plus (3). Twenty-three patients were in this group. This emphasizes the conclusion that a genital lesion is often lightly considered and no medical advice or treatment is sought until the organ is so distorted as to be useless. I have seen instances of destruction of the entire glans penis, for example, for which the patient had had no prior treatment.

I had surprisingly few recent secondary cases to deal with. Of the eighty patients under treatment sixteen were in the generalized secondary period. Among the skin lesions I saw one corymbiform syphilide, one circinate secondary lesion, examples of macular and papular syphilides, a number of recurrent secondary syphilides, and five men with condylomata lata. Mucous patches were also seen. In the majority of cases the patients had had no modern treatment and in all too many cases self-treatment alone had constituted the previous therapy. Three cases were diagnosed by the serological reaction. These cases were in the latent tertiary period and presented no lesions.

One patient was admitted for bed wetting. Clinically he presented no syphilitic lesions but the routine Wassermann reaction was four plus positive. Incidentally, arsphenamine therapy did not improve his sad condition.

Nine patients were admitted with active tertiary manifestations of syphilis. The age of the infection varied from two to eight years. This group of men presented gummatous infiltration of circumcision wounds, ulcerating groin adenitis, in one case gumma of the tongue, and in a second case, gumma of the shaft of the penis at the site of his primary lesion five years before (chancre redux).

The plan of treatment was on lines laid down

by Dr. S. Pollitzer (4). This plan I have termed the intensive method in distinction to the intermittent method. The intensive method consists of the daily administration intravenously of arsphenamine for three doses. Each dose consists of four decigrams dissolved in fifty c.c. of freshly distilled and boiled water, and then alkalinized to comparative neutrality with fifteen per cent. sodium hydroxide (5). This mode of treatment is a desirable variant of the *therapia sterilisans magna* of Ehrlich.

The theoretical reason for the failure of this method was that the single dose killed a large number of spirochetes but that some few escaped and later by multiplication were nearly as numerous as before, sensitized to arsenic and more dangerous. Another reason was that the excretion of the arsphenamine was begun almost as soon as injected and that in the first few hours most of the drug was out of the body.

The only figures we had access to were those in Wolbarst's (6) translation.

Paralytics given	0.3 gm. intravenously.
First day	0.0072 gm. arsenic found.
Second day	0.0792 gm. arsenic found.
Third day	0.0053 gm. arsenic found.
Fourth day	negative.

Investigations in other patients showed the same results, the excretion of arsenic having been completed within two or three days.

Since arsphenamine is essentially thirty per cent. arsenic, it appears that injected intravenously, ninety per cent. is excreted by the kidneys in the first three days. The intensive method counteracts both of these undesirable features because the concentration of the arsenic product in the blood is kept at an efficient high level. Following the intravenous medication, mercury salicylate in grain doses was given once each week.

It has been our experience that the negro is a bad subject for mercurial therapy because of the ease with which even small doses cause stomatitis. This occurs despite the care that the patients take of their teeth and gums. They used tooth brushes twice daily and the mouth wash after each meal. We painted the gums also with a mixture of equal parts of tincture of iodine and myrrh but the results were not gratifying subjectively. In bad cases we had the buccal cavity put into good condition before we administered mercury.

Although it is too early to speak of the end results of the intensive method for using arsphenamine, it is possible to note that the manifestations were speedily cleaned up. Uncomplicated syphilitic lesions disappeared within a very short time. Early chancres and condylomata lata were readily amenable. In other words the infectious lesions were soon destroyed. The patients that remained in bed for a long period were those with secondarily infected lesions, and syphilitics with other than syphilitic manifestations. In several instances of secondarily infected incised inguinal glands the intravenous therapy alone did not heal the lesion, but in several cases which gave fluctuation of a gland that was not incised, the intravenous medication relieved the swelling. In addition the general effect of this intensive therapy on the patient has been exceedingly gratifying.

We have seen no important ill effects. In one case, the second dose of the preparation we were using gave symptoms of intolerance and we interrupted the course. The drug which gave this was salvarsan, but on the same day eleven other patients received the same preparation without any ill effect. On odd occasions, a patient would vomit after partaking of the light repast provided six hours after receiving the injection. This did not contraindicate further use of the drug, but the patient went without his luncheon thereafter. The greater number of the patients received arsenobenzol (Schamberg) which gives remarkably few reactions of any kind. We find that this preparation dissolves more readily now than formerly.

SUMMARY.

Eighty hospitalized syphilitic negro men were given the intensive arsphenamine treatment as suggested by Pollitzer. The clinical results were immediate in all uncomplicated syphilitic manifestations. The infectiousness of the patient was reduced thereby much quicker than with the same amount of the arsphenamine introduced intravenously by the so-called intermittent method. The changes in serology were most encouraging, but no attempt is made to base conclusions on them. Reference to the former publications on this method will give information on this phase of the subject.

With no further precaution than that taken for the administration of arsphenamine intermittently, the eighty men were given this intensive form of treatment with excellent results, and we do not hesitate to recommend the procedure for more general use by those especially skilled in the application of arsphenamine as generally administered.

The public health value of this method of therapy should be emphasized since the period of hospitalization of infectious syphilitic persons is much reduced. This is an important consideration in the prophylaxis of syphilis by treatment.

Injections of Milk in the Treatment of Gonorrhea and Venereal Adenitis.—M. Trossarello (*La Riforma Medica*, April 3, 1920) has had excellent results in these conditions with the injection into the gluteal muscles of sterilized milk in doses of from five to ten c.c. Five injections were given at intervals of two or three days. There was in each case a marked reaction with elevation of temperature and local reaction which soon disappeared and was less marked after each injection.

FATAL POSTARSPHENAMINE JAUNDICE.*

BY ALBERT S. HYMAN, M. D.,

Boston,

Assistant Resident Physician, Long Island Hospital.

Toxic jaundice following the intravenous administration of arsphenamine, while not uncommon in large syphilitic clinics, is always of sufficient prognostic significance to command attention. A recent paper by Lynch and Hoge (1) has pointed out the paucity of medical literature upon this subject, especially in regard to the fatal cases which occur but rarely. These authors have collected a total of four fatal cases from an intensive survey of the literature; two reported by Fenwick, Sweet and Lowe (2), one by Veale and Wedd (3), and one from their own series.

In a review of several thousand doses of arsphenamine given at the Venereal Clinic of the Long Island Hospital we have been able to demonstrate seven cases of toxic jaundice which were undoubtedly due to this specific drug. All but one of the patients recovered, and since this is apparently the fifth case to have occurred, we believe it to be of sufficient interest to be recorded.

This case is made the more interesting in that the condition was produced by a single dose of arsphenamine, while the cases previously reported followed a series of intensive treatments. The patient remained in the hospital throughout her illness and this made possible an exceptionally complete study of her condition from every possible angle. Moreover, she appeared at a time when I was investigating the causes of the postadministrative reactions of arsphenamine (4) and for this reason the laboratory reports of her case are of considerable value.

CASE.—The patient (Hospital Number 40014) was a very well developed and nourished woman, thirty years old, weighing about 170 pounds, who entered the venereal service of the hospital for the treatment of gonorrhea contracted maritally. Her previous history was unimportant save that there was a suggestion of luetic infection from her story of frequent miscarriages.

Her physical examination was entirely negative except for a slight leucorrhea, a smear from which showed Neisser's organism in large numbers. A blood Wassermann was found to be positive and she was accordingly transferred to the syphilitic division for treatment.

On January 24, 1919, she received four tenths gram of arsphenamine intravenously. She suffered a slight immediate reaction with nausea and some vertigo, but on the following day she had entirely recovered. About five days later she began to complain of a general weakness and lassitude, the like of which she had never experienced before. With the exception of a slightly reddened throat her physical findings were negative. Laboratory examination of a twenty-four hour specimen of urine showed nothing of importance. All antisyphilitic treatment—mercury and potassium iodide—was stopped.

For the next two weeks the patient continued to

*From the Venereal Service of the Long Island Hospital.

grow weaker without any other signs developing; on February 21st, about one month after receiving the arsphenamine, she showed a slight icteroid tint in the scleræ. No bile was found in the urine. A well marked jaundice was seen the following day and bile was easily demonstrated in the urine; fecal bile was found in normal amounts. As the jaundice increased the prostration became more marked so that the patient was obliged to remain in bed.

At this time she began to complain of a terrific burning pain in the right thigh which was not well localized. Small areas of hyperesthesia the size of a silver quarter could occasionally be marked out upon the anterior surface of the thigh. On the following day, small purpuric spots were seen developing over the areas just described. The pain accompanying the development of these ecchymotic areas was so great that sedatives were required to comfort the patient.

From this time on purpuric areas continued to develop over all parts of the body. The jaundice was increasing in severity; the stools still contained bile, while the urine, of course, showed it in large amounts. There was apparently no change in the size of the liver or spleen. On February 26th the patient began to vomit bile stained fluid which microscopically showed little of interest. Purpuric spots then developed upon the mucous membranes of the mouth and pharynx and the vomitus gradually became coffee ground in appearance and was found to contain much blood. Occult blood was found in the stools.

Previous weekly examinations showed the blood to be normal. Examination at this time showed: erythrocytes 5,600,000; leucocytes 13,000; hemoglobin (Sahli) 100 per cent.; no erythroblasts, no anisocytosis or poikilocytosis. A differential leucocyte count showed: Seventy-four per cent. polymorphonuclears, twenty-five per cent. mononuclears, and one per cent. eosinophiles. Clotting time of the blood was found to be slightly increased. Blood pressure as at entrance was systolic 110, diastolic 75.

Urine examination: twenty-four hour volume 960 c.c.; dark brown in color; slightly alkaline, albumin found in small traces; no sugar; bile pigments in large amounts; no blood; Marsh tests for arsenic negative. Centrifuged sediment showed granular bile stained casts, a few epithelial cells and leucocytes.

Stool examination: formed, soft, dark brown, normal odor, no gross mucus or blood. Chemical examination: alkaline, bile present, occult blood found in large amounts, Marsh test for arsenic negative. Microscopic examination: many undigested meat fibres, unchanged fat globules in excess, many erythrocytes; no pus cells.

For a brief period the patient seemed to be getting better; the vomiting ceased, the patient looked and felt better. The jaundice continued to increase however, and on March 20th, she was forced to return to bed again. The weakness and apathy returned and the purpuric spots became more tender. A painful molar having developed, the dentist was consulted and he extracted four loosened teeth without great difficulty.

Due apparently to the great increase in the coagulation time of her blood, which upon test was found to be delayed forty minutes in comparison with a previous test which showed a delay of six minutes, the patient continued to bleed profusely from the gums. Application of local hemostatic solutions were of slight avail. During the night, the patient swallowed much of the blood and on the following morning vomited a considerable quantity of partially digested blood with some mucus.

The patient's condition became so poor that an immediate transfusion of whole blood was decided upon. Accordingly, Dr. L. H. Rockwell and myself, using the Kimpton tube method and securing about 450 c.c. of blood from a satisfactory donor, transfused the patient.

For a short interval following the transfusion, the patient's pulse and general condition seemed to be considerably improved, although the oozing from the gums still persisted. Subpectoral salt solution was given and a rectal tap apparatus started. The patient continued to go down hill, however, and after sinking into a semidelirious state died soon afterwards.

The postmortem findings so approximate those previously described by Lynch and Hoge as to be almost identical. They reported that "the postmortem examination revealed hemorrhagic phenomena in one or more of the viscera of all the bodies. In one of the cases the petechial hemorrhages were present in almost all of the viscera, but especially in the walls of the stomach and small intestines. There were a few points of hemorrhage in the kidney and visceral pleura. The other cases showed the walls of the stomach and intestine deeply injected. The pancreas seemed free from gross pathological lesions. Microscopically the kidneys showed a type of tubular nephritis much like that seen in cases of mercurial poisoning. The liver was small and mottled. It did not favor identically any of the more common types of cirrhosis. There was little or no fatty degeneration in any of the specimens examined.

The stomach in our case showed a large area of submucosal hemorrhage upon its lesser curvature. There seemed to be many small bleeding points near the pyloric end of this area which also showed numerous tiny varices. This would tend to indicate that the blood which was found in the vomitus was not due entirely to that which was swallowed.

The liver differed in some degree from previous findings in these cases. It was slightly larger than normal, and purplish red in color. The surface was smooth and resistant. The cut surface was essentially normal in appearance; there was no evidence of fatty degenerative changes. The gallbladder was large and filled with many stones; the ducts were patent and no obstruction of any kind was found. All of the tissues of the body were deeply stained with bile pigments. The spleen showed nothing of interest.

COMMENT.

The interest in these cases is focused upon the etiological factors responsible for the condition. To a great extent the symptomatology and pathological findings point incriminatingly toward the

employment of arsphenamine and the unusual response of the body toward the arsenic containing drugs. The story, however, is not a clear cut one either of acute or chronic arsenic poisoning. In the case just reviewed, the symptoms were late in developing and insidious in origin. It is somewhat difficult to believe that the small quantity of arsenic—about 122 mg.—which was contained in the first and only dose of arsphenamine that was administered, was capable of producing all of the subsequent symptoms and finally the death of a patient who apparently was in excellent physical condition prior to the beginning of her antisyphilitic treatment.

Previous writers have commented upon the unexpected histological picture found in the kidneys in these cases, and invariably they have described the renal findings as being comparable to those seen in mercuric poisoning. This suggests that there may be other factors concerned in the production of the condition. In all of the cases described the patients received both arsenic and mercurial medication and while it cannot be said that the picture presented in these cases is one of combined poisoning both by arsenic and mercury, yet it is not unbelievable that under certain rare conditions these two substances enter upon a synergistic relationship within the body.

The need of accurate experimental work along these lines is only too evident. Using such data as we have, however, it does not seem rational to classify these cases of toxic and fatal jaundice under the so-called idiosyncratic group—a group of unexplainable reactions which occasionally follow the use of arsenic. The importance of simultaneous mercury medication should not be forgotten, and it is not at all unlikely that the untoward symptoms and occasionally death itself which follow the administration of small doses of arsenic and mercury may be due to a mutual interaction of these two powerful agents upon the important organs of the body.

Different Spirochetes in General Paralysis and Common Syphilis.—A. Marie and Levaditi (*Presse médicale*, December 24, 1919) have made a comparative study of the local effects in rabbits of inoculation with virus from a syphilitic chancre and inoculation with virus from the blood of paretics. The viruses in the two instances were found to be different as regards period of incubation, duration of the lesions produced, appearance and pathogenic properties of the lesions, and crossed immunity. The conclusion reached was that there was probably a neurotrophic form of syphilis distinct from the ordinary, dermatrophic syphilis.

REACTIONS FOLLOWING INTRAVENOUS ADMINISTRATION OF ARSPHENAMINE.

The Influence of Atropine Sulphate and Adrenalin Chloride Upon These Reactions.

BY ALBERT A. STRICKLER, M. D.,
Philadelphia,

Associate in Dermatology, Jefferson Medical College; Assistant Dermatologist and Chief of the Dermatological Clinic, Jefferson Hospital; Assistant Dermatologist to the Philadelphia General Hospital, etc.

(From the Department of Dermatology and Syphilology of the Jefferson Medical College, Philadelphia, and in collaboration with Henry G. Munson, M. D., David M. Sidlick, M. D., and A. Strauss, M. D.)

While the symptomatology of the reactive phenomena at times attending the intravenous administration of arsphenamine has been carefully and systematically studied, the underlying causes of these reactions remain shrouded in obscurity, and the suggested preventive remedies have proved of but little value. Out of the great mass of theoretical considerations advanced relative to the reaction following the intravenous administration of arsphenamine only two factors stand out prominently and they are, first, those that relate to the patient and, second, those that relate to the medicament, i. e., arsphenamine. In another paper, we indicated that in our belief, arsphenamine might produce reactive phenomena, either as a result of some impurities in its composition, or due to some chemical interaction between the medicament (arsphenamine) and the elements of the blood, or both factors may be operative at the same time. Let us briefly review some of the more authoritative theories which have been suggested relative to arsphenamine reactions.

Soon after the employment of arsphenamine began, and reactive symptoms were being reported, Wechselmann announced his *Wasser-fehler* or water error theory as explanatory of the untoward symptoms. It was his belief that the decomposition of protein material in the water was the responsible factor. An extended experience has shown that while in a measure his contention has proved correct, it explains only a small number of the reactions encountered. In 1910 Neisser brought forth the hypothesis that the rapid killing off of spirochetes following arsphenamine injection, and the liberation of endotoxins which circulate in the blood stream, would account for the untoward phenomena encountered. In a recent paper we have proved that this theory is probably incorrect, as normal patients receiving arsphenamine intravenously report reactive symptoms in the same ratio as syphilitic patients receiving the identical serial number of the same make of arsphenamine, administered under exactly similar conditions. Among others McKee in 1912 observed that the injection of acid and partially alkalized arsphenamine solutions produced a precipitate and reactions. This observation has been abundantly confirmed by others.

Syphilographers have for a long time noted that the mental attitude of the patient treated exercises an important influence on the reactive symptoms. This psychic state we have observed, not only when administering arsphenamine, but also when injecting the mercurial preparations intravenously.

In 1917 Danyzs published his precipitation hypothesis as an explanation of the reactions following arsphenamine medication. In this hypothesis, Danyzs states that the carbon dioxide and sodium bicarbonate of the blood changes arsphenamine into an insoluble base which is carried in the circulation till dissolved by the leucocytes and the organic bases of the plasma. The biphosphates of calcium, sodium and magnesium, as well as the chloride and iron salts, are alleged to behave similarly. Schamberg and his associates, after an extensive study of Danyzs's theory, conclude that many of the hypotheses which Danyzs advanced are probably incorrect, stating as their belief that many of the reactions following arsphenamine treatments are due to some impurity in the arsphenamine, which they have not isolated as yet and which they have termed substance X. We must not lose sight of the fact that the reactions in some of our patients may be explained on the basis of a hypersusceptibility to arsphenamine (arsenic), and that this idiosyncrasy may act as either the sole cause or as the predisposing one.

A survey of the views herein expressed points to errors of technic, the syphilitic state of the patient, his mental attitude, the hypersusceptibility of the individual subjected to the treatment, impurities in the drug, and the interaction between the medication and the elements of the blood, all or some of these offering an explanation of the reactions following the administration of arsphenamine. In this study two drugs were administered intramuscularly and their ability to prevent the early reactions attending arsphenamine treatments noted. The medications employed were atropine sulphate and adrenalin chloride in a one in one thousand solution. Atropine sulphate was selected because of its well known inhibitory effect.

In our series atropine sulphate, one seventy-fifth of a grain, was administered intramuscularly about ten to fifteen minutes before the arsphenamine injections. A total of one hundred and one patients received the intramuscular injections of atropine sulphate and ninety-five patients were used as controls. Both groups of patients received the arsphenamine of the Dermatological Research Laboratories of the same serial number and administered under similar conditions. A statistical study of the reactive symptoms shows the following results: In the atropine series of one hundred and one patients thirty-four, or thirty-four per cent., reported absence of any reactions, while sixty-seven, or sixty-six per cent., complained of various reactive phenomena. In detail, twenty-two, or thirty-three per cent., complained of fever; twenty-nine, or forty-three per cent., of chills or chilliness; forty-five, or seventy per cent., of headache; thirty-nine, or fifty-nine per cent. of nausea; nineteen, or twenty-eight per cent., of vomiting, and sixteen, or twenty-three per cent., of diarrhea. In the control series of ninety-five patients thirty-one, or thirty-three per cent., were free from reactions, while sixty-four, or sixty-seven per cent., experienced untoward reactive symptoms. Out of this number sixteen, or twenty-five per cent., complained of fever, twenty-three, or thirty-six per cent., of chills or chilliness, thirty-seven, or

fifty-eight per cent., of headache, twenty-nine, or forty-five per cent., of nausea, twelve, or twenty per cent., of vomiting; and twenty-three, or thirty-six per cent., of diarrhea.

From these tables it is apparent that in so far as our series is concerned, the intramuscular injection of atropine sulphate had no appreciable influence for the prevention of the early reactive symptoms which may follow arsphenamine treatment. The percentage of patients reporting total absence of reactive symptoms was equal in both the atropine and control series, and although some differences were recorded in the percentage of the individual symptoms, such can readily be accounted for on the basis of individual peculiarity.

In another group of patients adrenalin chloride (1 in 1,000 solution) was injected intramuscularly in the dose of 0.5 c. c., a few minutes before the arsphenamine was administered. At first we attempted giving the adrenalin intravenously, but the symptoms which developed as a result of the injection were so alarming that this method of administration was discontinued. The total of ninety-seven patients received the adrenalin preceding their arsphenamine treatment, while forty-two patients received the arsphenamine alone. Both groups of cases received the arsphenamine of the Dermatological Research Laboratories of the same serial numbers administered under identical conditions. In the adrenalin series, twenty-four patients, or twenty-five per cent., were free of reactions, while seventy-three, or seventy-five per cent., reported some untoward symptoms. The following is the statistical study of the reactive symptoms reported: Fever occurred in twenty-six patients, or thirty-six per cent.; chills or chilliness in twenty-two, or thirty per cent.; headache in forty-nine, or sixty-seven per cent.; nausea in forty, or fifty-five per cent.; vomiting in sixteen, or twenty-two per cent.; and diarrhea in twenty-two or thirty per cent.

In our control series, there were forty-two patients, and of this number eleven, or twenty-six per cent, reported a total absence of reaction; thirty-one, or seventy-four per cent., reported untoward symptoms, which were as follows; fever in nine instances, or thirty-five per cent.; chills or chilliness in ten, or thirty-eight per cent.; headache in seventeen instances, or sixty-five per cent.; nausea in thirteen, or fifty per cent.; vomiting in seven, or twenty-seven per cent., and diarrhea in nine, or thirty-five per cent. Although Millian reported favorable prophylactic influence from the use of adrenalin in arsphenamine injections, our series seems to show the same percentage of reactions whether adrenalin was employed or not.

RÉSUMÉ

As a result of our investigation, we can conclude that the injections of either atropine sulphate in the dose of one seventy-fifth of a grain or adrenalin in chloride in the dose of 0.5 c. c. previous to arsphenamine injections, in no wise influences the occurrence of early reactive phenomena.

I wish to express my thanks to my assistants Henry G. Munson, M. D.; David M. Sidlick, M. D., and A. Strauss, M. D., for their cooperation during the course of this investigation.

THE VENEREAL DISEASE PROBLEM.*

BY THE HONORABLE WILLIAM RENWICK RIDDELL,
LL. D., F. R. H. S.,

Toronto, Canada.

President of the Canadian National Council for Combating
Venereal Disease.

It cannot be said that the subject to be discussed is one which is palatable or delightful, yet the situation must be faced and faced honestly and without flinching. We may not find it as pleasant to speak of the cesspool and the scavenger as of the rose garden and the gardener—and yet the one may be as important as the other, or vastly more so. There are diseases which are eating the heart out of our people, sapping their very life—unless well grounded estimates are gravely wrong half a million of Canadians are infected with the most serious form of venereal disease; in Toronto at least forty thousand, many, very many without knowing it. For one reason or another, the terrible extent of these diseases is not generally known—delicacy has been considered to forbid the discussion of them in public and those who suffer from them do not disclose their disease willingly. In insanity we know that until the other day it was considered not only a calamity but also a disgrace that any one of the family should be considered insane; a little of the same feeling lingers in respect of cancer and perhaps other diseases.

In venereal diseases there has been a widespread view that those who suffer from them are being punished for sin. That thought has prevented the members of the family of the affected from making known the state of their kinsfolk; and the stricken one himself has concealed from all eyes that he is stricken. But medical men have long known the extent of these diseases; and at length it has become absolutely necessary for the Government to take notice of them. It has long been cast up to governments as a reproach that in case of a disease attacking animals the utmost care and attention was at once paid to them but that when human beings were attacked little if any attention was paid to them. Whether that is true or not I do not enquire—the Governments, Dominion and local, are now awake to the terrible importance of venereal diseases. The Dominion Government has set aside two hundred thousand dollars to fight this powerful enemy of the human race and the Provincial Governments are also doing their share.

It was full time. In Britain the country was wide awake; in the United States the efforts of many agencies were bent to the extirpation or at least diminishment of the evil. In both these countries it was considered that the end could be best attained with the assistance of a national council, a semiprivate body acting in harmony with the central and local authorities, and our organization was called into existence for that purpose. I was honored by being made president of the council, an honor unexpected as it was unsought; and in view of the tremendous importance of the movement I could not refuse to give what assistance I could.

*Presented before the organization meeting of the Toronto Committee of the Canadian National Council for Combating Venereal Diseases, Toronto, March 24, 1920.

It is not the sinner alone who suffers—even if that were so the case would be hard enough—but the danger of infection is never absent from millions of the innocent; not a man, not a woman, scarcely even a child but runs the risk of infection every day. These we must in some way protect. Tuberculosis, smallpox, measles, scarlatina, all call for prevention and curative measures and such measures are promptly taken. Syphilis, which is more to be dreaded than any or all of these diseases, and is more common than any (except possibly measles), calls for more careful measures.

Think of the effect of syphilis: it affects about eight per cent. of the total population; is transmissible to the offspring and causes death in eighty per cent. of those infected; is the cause of ten to thirty-five per cent. of all insanity; of most mentally defective children; of locomotor ataxia; of paresis; of apoplectic and paralytic strokes in early life; of nearly half the abortions and miscarriages; of a large proportion of diseases of the heart, blood vessels and other vital organs. Syphilis decreases the length of life about a third and greatly decreases one's earning capacity during the remainder.

And what is very generally considered of trifling importance, "not much worse than a cold," gonorrhoea, while not so virulent, is still a deadly foe to the Canadian people, and is more common than syphilis. Gonorrhoea is the cause of more than ten per cent. of all blindness; of eighty per cent. of congenital blindness; of many surgical operations on the female generative organs; of many chronic diseases of the joints, bladder and generative organs, and this disease greatly decreases one's earning capacity.

These surely are enemies worth fighting—not in my time or in yours, not for generations to come will they be extirpated; but something, much, can be done by us in our generation.

We are not perhaps to expect that those who know themselves to be infected will do much for others—God knows they have a heavy enough burden of their own to bear—but I feel that I may call upon those who know themselves to be clean to help those less fortunate, and to assist those who are clean to remain clean.

The appalling versatility, the unearthly cunning of these diseases are such that thousands and tens of thousands have their seed within their bodies without knowing it, and I am well justified in saying that no man can be sure that today he is so clean and so immune from infection that he will be safe tomorrow. We intend to educate people, to make such investigation as will enable us best to educate the people while we are ourselves learning. We shall try to do all possible to prevent infection and to cure it where unhappily incurred.

Some Notes on Asexualization, with a Report of Eighteen Cases.—Martin W. Barr (*Journal of Nervous and Mental Disease*, March, 1920) presents a study of ancient literature upon asexualization and notes the various stages in the development of the practice for the mentally deficient and moral degenerates in state institutions of this country. A series of eighteen case reports sets forth in detail the actual results attained.

MEDICAL MEN IN THE AMERICAN REVOLUTION.

The New York Campaign of 1776.

BY LOUIS C. DUNCAN, M. D.,

Washington, D. C.,

Lieutenant Colonel, Medical Corps, U. S. Army.

(Concluded from page 460)

The encounter at White Plains took place on October 28th. The British attacked McDougall's New York Brigade, a part of which did not stand well, obliging the whole to fall back. Washington then retired to a stronger position near North Castle. The losses were not serious; less than a hundred in killed and wounded. As Morgan says, he cared for these wounded, both on the field, and in a sort of general hospital at North Castle. This double duty, instead of bringing about praise, seems only to have caused increased complaint: as he indicates:

Here I cannot but feel for the hospital surgeons, who before they could obtain any quarters, except such as a few hours' industry enabled them to do, in a country which was not well calculated to afford any good, were suddenly overwhelmed with numbers of sick sent them, as well as the wounded in time of an engagement, and whilst many of the regimental surgeons were absent in the country, having left their corps in the field without assistance, contrary to the orders of July 3rd; at a time when an engagement was considered inevitable there were few at hand to give any aid. Hence, while the hospital surgeons were preparing matters at their proper stations in the hospital, clamors were excited against them for not being with the troops; and when they were detained at the lines, to supply the place of regimental surgeons who ought to have been there, the wounded, who were conveyed to the hospital, naturally demanded the attention of the whole body of surgeons, to administer to them.

On November 5th he issued a circular requiring the surgeons to return to and remain at their proper places (17).

The action of Morgan at this time cannot be too highly commended. We shall see later how Shippen managed affairs at Trenton and Princeton.

When Morgan finally returned to North Castle he attempted to put the hospital in order there by constructing berths, building chimneys, etc., but could get little done. He states that some died from effects of cold, which was severely felt at that time—the latter part of November. Leaving what sick could be cared for at North Castle, in charge of Drs. Adams and Charles McKnight, he had the remainder (about a thousand) sent to Stamford and Norwich in Connecticut. That colony had established hospitals in all the principal towns between Hartford and New York. These too seem to have been taken over by the Congress. Morgan says that he visited both places in person, and that they handled nearly two thousand patients, refusing not a single one.

The hospital at Stamford was in charge of Dr. Philip Turner (18) and received in all about twelve hundred patients. Morgan says that it was well supplied, that the patients were comfortably provided for, and that most of them recovered. There is a letter from Dr. Turner, in November, recommending the discharge of 191 men at Stamford, as no longer fit for duty. On November 30th he again asked to have seventy-three discharged. He then said there were six or seven hundred in the

town, largely convalescents, but of whom not a fourth would be of any service. As the regiments to which they belonged were soon to be disbanded, he recommended that these men be discharged. Apparently this was done, for Morgan says that in February but twenty-five of the men remained in hospital. There is no account of any serious amount of sickness or many deaths at this hospital.

The hospital at Norwich was in charge of Dr. William Eustis. He reported that upwards of seven hundred sick and wounded were well provided for and attended with satisfaction. When he left Norwich, in March, 1777, but eight or ten remained. On December 10th, Eustis wrote to Heath, saying that he had four hundred sick, mostly convalescents. He was discharging the militia men and asked authority to discharge those belonging to Continental regiments also, as their terms of enlistment would soon expire. The authority was granted.

On November 13th all the troops of New York and the colonies south were on the Jersey side, at Hackensack, Amboy, Newark, Brunswick, and Elizabethtown. Morgan left New Castle and crossed the Hudson about November 12th. He found the army in rather a bad state and entirely destitute of hospital surgeons to take charge of the wounded in case of an attack. The resolution of October 9th, dividing the hospitals, was at first believed by him not to take away his general supervision. With Washington's permission he went to Philadelphia for the purpose of laying the matter before Congress and getting an explanation of the meaning of that resolution. He was unable to obtain an audience, and in a few days the Congress adjourned to Baltimore. He then returned to headquarters and there received a letter from a member informing him that it was the design of Congress that he should be restricted to the east side of the Hudson. He immediately started for his station, where General Lee now commanded.

On November 20th the British had landed six thousand men above Fort Lee. The garrison was withdrawn, losing two or three hundred tents, a thousand barrels of flour, and a few guns. On the 21st, Washington wrote from Hackensack saying that he had not above three thousand men, much broken and dispirited, with no intrenching tools, or other implements. He recommended that Lee come to his aid with his Continental troops, but did not order it. He then crossed the Hackensack, beginning his retreat. A return on November 23rd showed 5,410 men present for duty, but 1,360 were to be discharged on December 1st, and 950 more on January 1st. The Flying Camp was going to pieces. The condition of this army was desperate. On the 24th Congress authorized Washington to call the Pennsylvania and New Jersey regiments from the Northern Army; the Light Horse of Virginia, and the militia of Pennsylvania, known as the Associators. On this day Washington crossed the Passaic to Newark. The troops were without tents, poorly clad, marching wrapped in blankets, and presented a miserable appearance. The sick at Newark appear to have been sent to Morristown, and then to Bethlehem and other places.

During the latter part of October and five days

of November the movements of the British were a puzzle to the Americans. By threatening first one side and then the other, they had finally brought about a division of the Continental Army. On November 4th they retired toward the Harlem. On November 10th the division took place. General Lee was assigned to the troops east of the Hudson. He had seven brigades, thirty regiments, of New England troops. On November 24th his return showed 5,589 present fit for duty; 1,290 present sick; and 1,599 absent sick. General Heath was given three small brigades; also New England troops, for the defense of the Highlands. His headquarters was about Peekskill. He had on November 9th, 2,135 present fit for duty; 403 present sick; and 885 absent sick. Washington, with Greene, took all the troops from New York and the states to the south, for the defense of the Jerseys. At this time his force may have amounted to eight thousand men, but it decreased very rapidly, and on November 23rd he had but 5,410 present for duty. Of these, a third would claim their discharge on December 3rd, and a second third on January 1st, while the troops of Lee and Heath remained longer and were more promptly replaced.

On November 16th the blow fell at Fort Washington. After a doubtful defense, the post was surrendered with great stores and twenty-seven hundred prisoners. The force included Magaw's and Shea's Pennsylvania regiments, Rawlin's Maryland riflemen, and some militia from the Flying Camp. Dr. Hugh Hodge and Dr. James McHenry were among the prisoners (19) also Dr. John Beatty (20). The captures of the British at Long Island, Fort Washington and in various lesser conflicts now amounted to more than three hundred officers and 4,430 men. In this campaign they had captured almost as many men as Burgoyne surrendered at Saratoga. Fortunately for the Americans, then as since, men were their most plentiful war commodity. They were replaced, though the recruiting of men took time.

When the British (under Cornwallis) advanced on Hackensack, General Greene ordered the sick sent to the country. They went in various directions; about a hundred of Colonel Bradley's regiment went to Fishkill, where the New York Council of Safety authorized Dr. Chauncey Graham to care for them in the unfinished academy. When the army was divided General Heath, with the smaller division, was left without a general hospital. On November 19th he wrote a letter making a proper complaint (21). Morgan, then at North Castle, rode up to Peekskill, and interviewed Heath on the subject of a hospital and surgeons. He offered to furnish the surgeons and fit up a hospital for three hundred sick, as soon as the building should be ready (22). When he called on the quartermaster for workmen and material to put the buildings in order, build chimneys, construct berths and other necessary equipment, the quartermaster replied that every man was on some necessary work, and recommended that he apply to General Heath. Morgan did so, and the reply received was, "That the General did not choose to meddle with anything to be done in the quartermaster general's department."

This is a sample of Morgan's difficulties, here, at Hackensack, and other places. Dr. Adams and Dr. McKnight were sent to Peekskill, but as no buildings were available the sick had to be taken twenty miles across the Highlands to Fishkill. On December 5th the New York Convention informed Heath that barracks for two thousand men were being constructed between Peekskill and Fishkill; that the sick could be cared for in some of these, and that more would be built if necessary.

The year was drawing to an end and with it Morgan's service as medical director. On January 9th, 1777, Congress, without consulting Washington and without giving any hearings, passed a most unjust resolution dismissing both Morgan and Stringer from the army. (23.) A later committee found that there was no charge against Morgan's character or ability, but his reputation was irretrievably injured, and he was left a disappointed and broken man; sacrificed as a sort of scapegoat, on account of public clamor, for faults more chargeable to Congress than to himself.

The political game was played and Morgan was thrown to the wolves. His tireless energy under every discouragement; his faithfulness and economies; his integrity of character which made work for the sick and wounded, not personal favor, the goal—all were forgotten. It is true that the hospitals had sometimes failed. So had every department of the army, and the army itself, failed. Treat every man according to his deserts, as measured by success, and they had all been hanged. The commissary failed, the quartermaster failed, the whole army was beaten in every battle, outmaneuvered and outwitted; at the last of the year it was a wreck which Washington himself said would come to an end within ten days.

Little credit can be claimed for the General himself in the actual management of this, his first campaign. All were amateurs pitted against professionals. All had to learn the difficult art of war through the costly lessons of failure. The real encomium of all is, not that they had any success, but that they stood steadfast in the face of continual defeat. Any fair comparison will prove that the Medical Department of the Continental Army was handled as well as any other department. But, following the custom of politicians, public clamor had to be appeased by a sacrifice. Morgan was even informed that he was not dismissed on account of any particular act or omission, but because of general complaint. That he was given no hearing, no chance to defend himself, only accentuated the meanness of this act of injustice.

The New York campaign actually came to an end when Washington and then Cornwallis crossed the river into New Jersey. The contest was thenceforth for the Jerseys, possibly Philadelphia. The Continental Army was fatally divided. Gates had above five thousand troops for duty at Ticonderoga; Lee had as many east of the Hudson; Heath had three thousand in the Highlands. Washington probably had the weakest force of all, about five thousand, of whom only half were Continentals.

This campaign had been very near a total failure. Every battle had been lost; New York surrendered;

nearly five thousand of the army had been taken prisoners; and toward the end the men had not stood well in battle. Yet in the whole series of battles less than a thousand men had been killed and wounded. Probably not more than two hundred had been killed or had died of wounds, and six or seven hundred wounded who recovered. Of the five thousand prisoners at least half died of disease and neglect. It is impossible to make even a reliable estimate of the losses from disease from the time the army reached New York until the end of the year. I do not believe that five thousand would be at all high. At least as many more were lost in the Northern Army. The battle losses (killed and wounded) of that army were also very small, little if any more than five hundred. The British had taken a thousand prisoners, most of whom were reasonably well treated and returned by exchange. Those officers captured at Quebec in December, and at Three Rivers in June, reached Elizabethtown, New Jersey, in September.

The sufferings of American prisoners of war in New York were long the subject of bitter complaint. The prisoners taken on Long Island, at Fort Washington, and elsewhere were crowded into buildings in the city and into old hulks in the harbor, where under the worst sanitary conditions they died by hundreds. Both smallpox and typhus contributed to the death roll of these wretched victims of the war. In the city the principal prisons were: the Middle Dutch Church on Nassau Street, afterward the Post Office; the Lutheran Church, at the northeast corner of Frankfort and William Streets; the old Provost Prison, converted into the Hall of Records in 1831; the Huguenot, the Brick Church, and the Friends' Meeting House; the Van Cortlandt Sugar House; another near the Dutch Church; and the Rhinelander Sugar House, at the corner of William and Duane Streets. In all these places the sufferings were intense. "I have gone into a church," writes Colonel Ethan Allen, "and seen sundry of the prisoners in the agonies of death in consequence of very hunger, and others speechless and near death, biting pieces of chip. . . . The filth of these churches was almost beyond description. I have seen in one of them seven dead at the same time." Three thousand were crowded into the Dutch Church, but an outbreak of smallpox compelled their removal. Colonel Ethan Allen, Major Travis of Virginia, Judge Field of Bergen, Major Van Zandt and others of rank were subjected to the brutality of one Captain Cunningham, who boasted that he had starved two thousand rebels by selling their rations.

The treatment of military prisoners at that time was generally inhuman. It was the more so in the case of the colonists who were considered as rebels, to be punished as well as imprisoned.

Clothed in rags and scarcely covered from the wintry air, crowded in narrow rooms and weakened by disease, the prisoners died by the hundreds. The feeble shivered in the wintry blast, the sick lay down on beds of snow to perish. Food was of the coarsest kind and was served out in scanty measure. Smallpox and the deadly jail fever raged unopposed. Every night ten or twenty

died; every day the meagre bodies were thrown into pits, with no burial rites. Even when led out for exchange there was little hope, for many died on the way home, or lingered on for but a few miserable weeks. So wretched was the condition of these exchanged prisoners that Washington refused to consider them fit subjects for exchange. "You give us only the dead or dying," he wrote to Howe, "for our well fed and healthy prisoners," and pointed to the condition in which they reached him, diseased, famished, emaciated and dying, as they were conducted to their quarters.

The *New Hampshire Gazette* of April 26, 1777, said:

The enemy in New York continues to treat the American prisoners with great barbarity. Their allowance to each man for three days is one pound of beef, three wormeaten biscuits, and a quart of salt water. The meat they are obliged to eat raw as they have not the smallest allowance of fuel. Owing to this more than savage cruelty, the prisoners die fast, and in the small space of three weeks (during the winter) no less than 1,700 brave men perished. Lieutenant Collin narrates that he with 225 men were put on board the *Glasgow* on the 25th of December, 1777, to be carried to Connecticut for exchanges. They were on shipboard eleven days, crowded between decks, and twenty-eight of their number died through illness in that brief space of time.

The contagion of the prisons did not fail to spread to the city. During the winter the smallpox made fearful ravages. Hundreds of the citizens died, and the wealthy fled in fright to their country homes, to undergo inoculation. The violent putrid fevers of the prisons spread to the inhabitants. New York was full of mourning. Of thirty persons in one family only ten escaped. The graveyards teemed with burials. The summer air brought no relief, but seemed malarious and deadly.

Terrible as were the conditions in these prisons, they were even worse on the prison ships: old hulks moored near Wallabout Bay. The most notorious of these was the *Jersey*, whose evil repute is scarcely less than that of the Black Hole of Calcutta. Her guard was composed of Hessians. Frequently a thousand Continental soldiers were confined on board, and there they sickened and died by hundreds. At night the hatches were battened down, in the morning the jailers shouted, "Rebels, turn out your dead." No aid could be extended to them, not even medical service.

These facts are recorded merely to show the price paid by the colonists for liberty; that the people of today may not forget the sufferings of those who, going forth to battle for freedom, died in misery and filth in these horrible prisons; aiding, however, in securing that freedom for us.

During the year 1776 there were in service forty-seven thousand Continentals, one year troops; and twenty-seven thousand militia, who served from a few days to a few months, some near a year; so many never enlisted in one year again. Their casualties may be estimated roughly at one thousand killed or died of wounds, twelve hundred other wounded, six thousand taken prisoners, ten thousand died of disease, and several thousand who deserted or disappeared. At the end of the year the term of enlistment of nearly all expired. Some few regiments had been organized later than others;

some were persuaded to remain a few weeks beyond their terms of service; but the main Continental Army disappeared, the new one was not yet formed, and the often reviled militia had to fill the gap, as at Boston the year before. Fortunately for the country, the British Army followed its time honored custom of going into winter quarters. No offensive movements were made after December. Time was thus given to organize a new army and to prepare for the next year's campaign. Congress had already provided the necessary legislation, and recruiting was in progress. That the work could be done in the face of general defeat and failure throughout the year is an enduring memorial to the faith and steadfastness of the struggling colonists.

NOTES.

12.—DR. MORGAN TO GENERAL WASHINGTON.

NEW YORK, *September 12, 1776.*

Agreeable to orders I have been in the County of Orange and collected seven members of the Committee and spent the whole of yesterday and part of this day in viewing the country, and looking out for proper covering for the reception of the sick and wounded.

I am sorry to report that in a circuit of fourteen miles in that County, I cannot find or hear of any suitable accommodations for more than about one hundred sick. No country can be worse provided in all respects; and the places proposed are remote from any landing. From the knowledge I have of New Ark I am persuaded it is a place infinitely superior in all respects for the establishment of a general hospital. There are but four miles of land carriage required; all the rest is water carriage. The houses are numerous, large and convenient. If it be objected that they are full of inhabitants from New York, so is every hovel through Orange County; and as to the town of Orange, I cannot find that there is room for one sick person without incommoding some one or other.

After this report, which is grounded on the most careful inquiry and inspection, I await your Excellency's further orders; but if I may be permitted to offer my sentiments it is that no time be lost in applying to the Committee at New Ark by requisition for room for the sick; and if your Excellency thinks proper, I will immediately repair with all despatch to urge the matter without delay, or proceed in any other way your Excellency may see fit.

I am your Excellency's most obedient and very humble servant,

JOHN MORGAN.

13.—Dr. William Burnet, of Newark, New Jersey, was a member of the Committee of Public Safety of that Colony, and was made Surgeon General of the militia, February 17, 1776. His son, Ichabod Burnet, was an aide of General Greene. When Mrs. Washington journeyed to Cambridge in 1775 she stayed at the house of Dr. Burnet in Broad Street. He was Physician and Surgeon General of the Eastern Department, April 11, 1777, and Hospital Physician and Surgeon, Oct. 6, 1780; and Chief Hospital Physician and Surgeon, March 5, 1781 to the end of the war. He was stationed at West Point at the time of Arnold's treason; after the war, was president of the State Medical So-

ciety, and Judge of the Court of Common Pleas. A son, David Burnet, became President of Texas. Dr. Burnet died October 7, 1791.

14.—RESOLUTION OF CONGRESS.

Resolved. That no regimental hospitals be in future allowed in the neighborhood of the general hospital.

That John Morgan, Esq., provide and superintend a hospital at a proper distance from the camp, for the Army posted on the east side of Hudson's River.

That William Shippen, Esq., provide and superintend a hospital for the Army in the State of New Jersey.

That each of the hospitals be supplied by the respective directors, with such a number of surgeons, apothecaries, surgeons' mates and other assistants; and also with such quantities of medicines and bedding, and other necessaries, as they shall judge expedient.

That they make weekly returns to congress, and to the Commander in Chief, of the officers and assistants of each denomination; and also the number of sick and deceased, in their respective hospitals.

That the regimental surgeons be directed to send to the general hospital such officers and soldiers of their respective regiments, as confined by wounds, or other disorders, shall require nurses or other attendance, and from time to time apply to the Quartermaster General, or his deputy, for convenient wagons, for their purpose; also, that they apply to the directors in their respective departments for medicines and other necessaries.

That the wages of the nurses be augmented to one dollar a week.

That a commanding officer of each regiment, be directed once a week to send a commissioned officer, to visit the sick of his respective regiment, in the general hospital, and report their state to him.

CHARLES THOMPSON, Secretary.

15.—LETTER OF WASHINGTON TO CONGRESS.

Before I conclude I would beg leave to mention to Congress, that the pay now allowed to nurses for their attendance on the sick is by no means adequate to their services—the consequence of which is that they are extremely difficult to procure; indeed they are not to be got, and we are under the necessity of substituting in their place a number of men from the respective regiments, whose services by that means is entirely lost to the proper line of their duty, and but little benefit indeed to the sick. The officers I have talked with upon the subject all agree that they should be allowed a dollar a week, and that for less they cannot be had. Our sick are extremely numerous, and we find their removal attended with the greatest difficulty. It is a matter that employs much of our time and care, and what makes it more distressing, is the want of proper and convenient places for their reception. I fear their sufferings will be great and many; however nothing on my part that humanity or policy can require shall be wanting to make them comfortable, so far as the state of things will permit it.

I have the honor to be &c.

GEO. WASHINGTON.

16.—TO DOCTOR BENJAMIN RUSH MEMBER OF THE
MEDICAL COMMITTEE OF CONGRESS.

Sir: By command of General Washington, all the sick and wounded, both in the general hospital and those remaining under the care of regimental surgeons, are removed within two days, to this side of the river, and chiefly in this neighborhood. They amount to several hundreds, in addition to about 300 who were before removed to Newark, and 4 or 500 in Orange County.

The general's commands were to leave a respectable body of surgeons and mates above Kingsbridge, a general action being daily expected, as the whole force of the enemy is drawn to that quarter.

So soon as I get this part of the general hospital into order I am to return and provide accommodations at the White Plains, for which indeed I gave the necessary orders before I came over.

JOHN MORGAN.

17.—CIRCULAR LETTER.

To the regimental surgeons and mates, belonging to the Army of His Excellency, General Washington, now absent with, or without the sick of their respective regiments and brigades, on either side of Hudson River. Gentlemen:

Few of the surgeons or sick, allowed to remove from camp some time ago, being yet returned, and no report being made of them to me, His Excellency the Commander in Chief, conceives that his former indulgence to the sick, in permitting them to retire from the camp for the recovery of their health, has been much abused both by the sick and the generality of the surgeons and mates, under whose care they were allowed that indulgence; it is His Excellency's orders, therefore, that each of you do forthwith wait upon Isaac Foster, Esq., at Hackensack; John Warren, Esq., at Newark, or Philip Turner, Esq., at Norwalk; Surgeons in the general hospital, whoever of them is nearest at hand, and make a faithful and accurate report of the sick and wounded under your care, and remove those who are fit subjects, immediately, to the general hospital, under their care; for which you are to apply to the quartermaster general's dept. for wagons, and accompanying them yourselves

Such of you as those gentlemen require to assist them for the present in the general hospital, and who are willing to attend to their sick there, under their direction, are allowed to do so till further orders; all others are to repair immediately to headquarters, and join their respective regiments: first furnishing me with an accurate register, duly certified, of the state of the sick that went out with them, or have been since under their care, specifying the time of their being taken ill, their diseases, and events as to death, recovery, or continuance; and whether any of the sick have been allowed to withdraw from under their care, and when.

As all who are absent without leave must naturally be looked upon as deserters. And the surgeons, or mates, who cannot give a regular and satisfactory account of the faithful discharge of their duty, necessarily subject themselves to an inquiry into their conduct.

JOHN MORGAN.

18.—Philip Turner was born at Norwich, Connecticut in 1740. Being left an orphan at twelve, he was taken into the family of Dr. Elisha Tracy and in time studied medicine. In 1759 he was an assistant surgeon with a provincial regiment at Ticonderoga: continuing with the army until 1763. At the beginning of the war he stood at the head of his profession, but left his practice to become surgeon of Huntington's Regiment (8th Connecticut, later the 17th Continental). He was at Boston, accompanied the army to New York, and was at Long Island and White Plains. In 1777 he narrowly missed being made Director General instead of Dr. Shippen. He was a little later made Surgeon General of the Eastern Department; and served as such until near the end of the war. He then returned to Norwich and resumed practice. In 1800 he removed to New York City, and later was appointed a staff major in the army, with station at Governor's Island. He held this position until his death in 1815.

19.—Dr. James McHenry was born in Ireland in 1753, came to America in 1771, studied medicine in Philadelphia under Dr. Benjamin Rush, but does not appear to have graduated from the Medical College. He was made surgeon of the 5th Pennsylvania Regiment on August 10, 1776, and was taken prisoner at the capture of Fort Washington, November 16, 1776. He was on parole until exchanged, March 5, 1778. In May he was appointed secretary to General Washington, and this ended his medical career. On May 25th he was commissioned a major in the Continental Army. In 1780-81 he was an aide-de-camp to LaFayette. After the war he was a member of the Maryland Legislature. He was Secretary of War from January 29th, 1796, to May 13, 1800. Fort McHenry, Baltimore, the scene of the incident giving rise to the writing of The Star Spangled Banner, was named in his honor. He died May 8, 1816.

20.—John Beatty was a native of Bucks County, Pennsylvania, where he was born in 1748, but received his education in New Jersey and lived in that State for forty years. He graduated from Princeton College in 1769, and afterward studied medicine under Dr. Rush. Like many other medical men, at the beginning of the war he exchanged the civilian dress of the surgeon for the regimentals of a line officer. By September of 1776 he had reached the rank of lieutenant colonel. Fickle fortune placed him in one of those Pennsylvania regiments selected to defend Fort Washington. As they were unable to defend it, he became a prisoner of war, and as such endured great hardship and suffering. He was not released until his health had entirely failed, requiring several years for restoration. Not until 1779 was he able to resume active duty. He was then appointed Commissary General of prisoners, which position he is believed to have held until the close of the war.

[Notes 21, 22 and 23 have been omitted, owing to lack of space; they will appear in the author's reprints. Notes 21 and 22 comprise a letter from General Heath to Dr. Morgan and Dr. Morgan's reply; Note 23 embodies the resolution dismissing Dr. Morgan from the service. EDITORS.]

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL

INCORPORATING THE

Philadelphia Medical Journal and the Medical News

A Weekly Review of Medicine.

Address all communications to
A. R. ELLIOTT PUBLISHING COMPANY,
Publishers, 66 West Broadway, New York.

Subscription Price: Under Domestic Postage, \$6; Foreign
Postage, \$8; Single copies, fifty cents.

Remittances should be made by New York Exchange, post office
or express money order, payable to A. R. Elliott Publishing Co.,
or by registered mail, as the publishers are not responsible for
money sent by unregistered mail.

Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, SATURDAY, OCTOBER 2, 1920.

OCULAR ACCIDENTS ATTRIBUTED TO ARSENICAL PRODUCTS.

The arsenical compounds, both mineral and organic, have been the cause of various accidents, but ocular disturbances attributed to these products are the most serious of all. The arsenical products that have produced slight ocular accidents having a good prognosis are the cacodylates and sodium and potassium arsenate; those producing serious disturbances are atoxyl, arsacetine, hectine and hectargyre, as well as salvarsan and neosalvarsan.

Regardless of the very extensive use made in recent years of the cacodylates lesions of the optic nerve have never been recorded. The few cases reported of optic neuritis following the internal exhibition of sodium or potassium arsenate have been neuritides presenting the type of toxic neuritis or infectious neuritis with a central scotoma, without any change in the peripheral visual field but offering a slight irregularity in the outline of the papilla. The prognosis is favorable in these cases.

Atoxyl produces complete and incurable atrophy of the optic nerve following a retrobulbar neuritis, the symptoms being a narrowed visual field, decrease of the pupil reflex, white papillæ and a narrowing of the vessels of the retina. Arsacetine acts in the same way only its toxicity is somewhat less. Hectine and hectargyre produce identical lesions of the optic nerve but nevertheless not so serious as those resulting from atoxyl.

However, all things considered, ocular complications have been reported too frequently from these

products so that preference should be given to salvarsan, arsenobenzol or neosalvarsan. The ocular accidents attributed to salvarsan may be placed in three categories, namely, accidents in the uveal tract, those of the optic nerve, and accidents arising in the motor nerves, the globe of the eye, and the eyelids.

The accidents arising in the uveal tract—iritis and choroiditis—attributed to salvarsan are, in reality, merely syphilitic manifestations and are not the result of the drug. Their early appearance is proof of this. Likewise, the optic neuritis attributed to salvarsan would seem also to be of a syphilitic nature; it is neither more frequent in occurrence nor earlier in appearance than before salvarsan came into use.

As to the disturbances of the motor nerves of the eye they are simply manifestations of the syphilitic virus and cannot be attributed to salvarsan. The cases recorded by Bizard, Sicard, Guttmann, and others were due to meningeal phenomena which reacted upon the cranial nerves as might be expected; these meningeal phenomena were noted at the very onset of the syphilis and before treatment with salvarsan had been given.

It is also safe to assume that what has been said of salvarsan applies as well to neosalvarsan, arsenobenzol and other recent products of arsenic, and that with very small doses repeated daily or every second day, either subcutaneously or intravenously, no accidents of any description need be feared.

SLEEPING SICKNESS.

Sleeping sickness has been confounded to some extent with encephalitis lethargica. When the latter condition was somewhat prevalent in this country, the daily journals usually referred to it as sleeping sickness. According to H. L. Duke the date of commencement of the great epidemic of sleeping sickness on the shores of Lake Victoria is difficult to determine. The attention of Europeans was first drawn to the disease in 1901, but inquiry among the Buganda chiefs revealed the fact that *mongota*, the native name for the disease, existed previous to this date in endemic form. In 1906 Sir H. Hesketh Bell proposed a scheme for dealing with the malady which was put into execution. Segregation of the infected was the principle of this scheme and was commenced in 1906, and by the end of 1907 the mainland population had been removed inland for a depth of two miles from the coast. These measures were enforced only within the limits of the Uganda protectorate.

Different means of endeavoring to extirpate the disease prevailed in the adjoining fly areas of German East Africa and British East Africa. The Germans combined deforestation measures with a limited depopulation scheme applied to certain dangerous localities. In British East Africa the natives were left in contact with the flies, an attempt to encourage voluntary segregation and isolation proving abortive. Along the shores of the Kavirondo Gulf, the epidemic apparently worked itself out after causing a very heavy mortality. The disease in this area now appears to be endemic and the population is reported to be increasing. As for German East Africa, the authorities there described the measures taken as completely successful yet admitted that isolated cases of fresh infection occurred from time to time.

Concerning the part played by the tsetse flies in the transmission of the infection, as a result of most careful and critical examination of all available information with regard to the Uganda epidemic Duke brings forward the hypothesis that mechanical transmission from man to man of a virulent strain of *Trypanosoma gambiense* played a most important part. He points out that the conditions necessary for direct transmission, viz., the presence of many large biting flies and of many potential hosts of the parasite in close juxtaposition, were fulfilled in the closely packed canoes of Victoria Nyanza. However, the chief point raised by Duke is as follows:

While it appears that segregation had its effect in Uganda, in preventing the spread of the disease, nipping it in the bud in fact, does it follow that those responsible for the direction of affairs in that district of Africa are justified in accepting the most obvious interpretation and proceeding to reconstructive effort on the assumption that an epidemic of sleeping sickness is impossible unless there is sufficient contact between the flies and the population to render possible the development of a virulent mechanical transmission strain, or must the possibility also be taken into account that the pathogenicity of the trypanosome may be subject *per se* to variations, irrespective of the method by which it is transmitted? On the latter explanation the disappearance of acute trypanosomiasis in Uganda is not altogether due to the preventive measures but also in greater or less degree to diminution in pathogenicity of the parasite, and the trypanosome is likely to resume a virulent state, even in Uganda, under existing conditions. Duke, therefore, considers that further specific inquiry is needed to elucidate the question. Reading the results of such inquiry the following hypothesis affords the best answer that can be given to what may be regarded as the

main question. It recognizes the possibility that the trypanosome may vary greatly in pathogenicity to man; it takes into account the manner in which peculiarly virulent strains of normally less virulent species of insect borne trypanosomes are developed; it recognizes also the real probability that such strains may develop in nature as well as in the laboratory; it recognizes a clear possibility that a peculiarly virulent strain of trypanosome may have been developed in this manner; and finally, if it could be proved well founded, it would indicate that very broad contact between the flies and the population is a prime essential to the occurrence of sleeping sickness in the form of a widespread epidemic. The inquiry recommended by Duke should be valuable not only with regard to sleeping sickness but with respect to other insect borne diseases and perhaps disease generally of an infective character.

PHYSICIAN AUTHORS—JOHN LOCKE.

The most important figure in English philosophy is Dr. John Locke, a physician whose *Essay on Human Understanding* has been, ever since its publication in 1690, one of the two fountain heads of modern philosophy. The other is Kant's *Kritik of Pure Reason*. What Kant is to German philosophy Locke is to English. These are the two giants of modern philosophy. Locke's *Essay*—that is all the title it generally gets in discussion—gave a new direction to European philosophy and provided a new basis for the science of psychology. It opened a better and clearer way to reasoning. John Stuart Mill, Locke's spiritual descendant, called Locke the "unquestionable founder of analytical philosophy of the mind," and D'Alembert says: "It may be said that he created the science of metaphysics, for he reduced metaphysics to that which it ought to be, viz., the experimental physics of the mind." Henry Hallam is equally enthusiastic. He describes the essay as "the first and most complete chart of the human mind laid down; the most ample repertory of truths relating to our intellectual being and the one book which we are still compelled to name as the most important in metaphysical science."

But the essay has its inconsistencies and these have been assailed as hotly as its truths have been defended. It is not the individual doctrines, however, that give it its superiority. Many of these have succumbed to hostile criticism. The excellence lies rather in the general drift and the direction it gave to the philosophical studies of others. "There is hardly a single French or English writer (and we may add Kant) . . . who does not profess either to develop Locke's system, or to supplement,

or to criticise it," says Thomas Fowler. In short, around this essay a whole literature of attack and defence has arisen. "He suggests as much as he teaches," says George Henry Lewes, and it is not to be denied that the essay opened up vast tracts of thought and has had an enormous influence, despite its weaknesses.

It took Locke twenty years to write this splendid textbook of what has been called "the noblest branch of human learning." Twenty years of concentration and toil whenever he had the time, and he got only thirty pounds for the copyright. Purchase of the most renowned treatise of its time, the greatest book of its generation, for a miserable pittance of thirty pounds! Many an author today would spurn this amount if it were offered for a trifling short story sketched during one weekend and completed before another.

George Henry Lewes says Locke's education as a physician fitted him for the meditation necessary to write the essay, and other writers have assured us that his medical observations had a powerful influence on his speculative studies. Locke was one of the most renowned physicians of his day, although he was one of the late blooming variety. It was not until he was forty-two years old that he took his degree of Bachelor of Medicine, in 1674. This was because when he first went to Oxford he studied theology, and it was only after several years of classical and theological study that he determined to be a physician. His chronic ill health also delayed his medical studies. He was afflicted with lung trouble and on two occasions had to take extensive rests in southern France. It was his good fortune to have a lord as his first patient, Lord Ashley, afterwards Lord Shaftesbury, whose life he saved. The two were fast friends forever after and their names are linked in politics, in which Locke took such an active interest that he had to flee to Holland, where he spent five years in exile under the assumed name of Dr. Van der Linden. It was while he was in Holland that he completed the essay. His exile weighed heavily upon him, we are told, but at the end of it fortune smiled upon him and through the influence of friends he held several highly paid government positions.

The *Essay on Human Understanding* was but one of many writings on which Locke's fame rests. He wrote four other philosophical treatises of lesser consequence, five on Christianity, eight on social economy, five on education and several on miscellaneous subjects. Perhaps second in importance was his *Essay on Tolerance*, in which he is credited with having uttered more good sense on the subject of religious tolerance than is found in the works of

any preceding writer. It came at a time when the spirit of toleration and charity in religious differences was badly needed and it wrought much improvement. Carlyle said of it that "it paved the way for banishing religion from the world," but that, perhaps, may be an overappreciation of its influence. By means of his *Essay on Education* Locke became a great educational reformer, changing the whole attitude of English and continental society toward the subject. His *Essay on Government* diffused throughout the world the love of civil liberty. This essay was the first on which his name appeared. *The Essay on Tolerance* and many of the others appeared anonymously.

John Locke was born in Somersetshire, England, on August 29, 1632, six years after the death of Bacon, and died in 1704 at the age of seventy-two. In the inscription on his tomb, prepared by himself, he refers to his books as a true representation of what he was. "If we consider his genius and penetrating and exact judgment, or the strictness of his morals, he has scarce any superior and few equals," said Dr. Thomas Sydenham, the famous physician after whom the Sydenham society was named, in his *Medical Observations*.

THE BRITISH NATIONAL INSURANCE ACT.

It was shown at the recent meeting of the British Medical Association that much discontent prevails among the members of the British medical profession generally with regard to the National Insurance Act. Perhaps it is not so much a question of remuneration, although the pay of panel practitioners is by no means too liberal, as the comparative loss of independence and the fear that they may be under the thumb of the societies. The British medical profession is almost a negligible quantity politically, whereas the societies are immensely powerful. The societies are antagonistic to the medical profession, regarding its members as belonging to the privileged classes. In the *Medical Press*, August 25th last, is an article entitled *Some Thoughts on the National Health Insurance Act and the Panel*, by Dr. James Hamilton, who gives an opinion of the matter which probably is also the opinion of many a practitioner. The main objection that the writer brings against the panel system is the loss of liberty and individuality that the doctor suffers. He points out that new rules and regulations and new rulers and a new agreement came along on April Fool's day, and since then a new act, which is like its predecessor in being only a skeleton to be completed by orders in council and regu-

lations. The panel practitioners are therefore ignorant of what is in store for them in the future. The writer goes on to point out that if there was anything like accurate bookkeeping between the societies and the insurance committees it ought to be possible, seeing that the act has been in force for about seven years, for an insurance committee to be able to tell the doctor that there are so many on his list at the end of each quarter and so much a quarter will be paid for each one.

The act simply bristles with absurd and irritating regulations, but the great objection to it from the medical man's point of view is that he is, to some extent, now under the domination of the approved societies, and it looks as if this domination would not grow less but greater. Many medical men fear that it is the insertion of the thin edge of the wedge leading to nationalization of the medical profession, and when the labor representative who attended the meeting of the Sociological Section of the British Medical Association, held recently in Cambridge, stated outright that he was in favor of nationalizing the profession, this fear appeared to be justified. There has been much talk in the United States of late of having an insurance act and placing a goodly proportion of the medical men on a similar status to that held by the panel practitioners of Great Britain. It will be as well if doctors here move cautiously, and make sure that they are not sacrificing liberty before pledging themselves to any such course. It is better to endure the ills we know, than to fly to those we wot not of.

OSLER MEMORIAL NUMBER.

What will prove a valuable historical publication in the medical world is the Sir William Osler Memorial Number of the *Canadian Medical Association Journal* of July, 1920. There are several portraits of Sir William, notably one at the time he was prefect in Trinity College School; Osler as a student of medicine at McGill University in 1871; the handsome, debonair Osler in 1881; Osler at Oxford in 1908. Relatives, personal friends, classmates, students, distinguished men of science, confrères in practice, faculty associates have contributed to this volume which should have been presented to the profession in other than regular journal covers.

There is a foreword by Dr. Francis J. Shepherd, classmate and lifelong friend; the memorial sermon by the Reverend H. Symonds, Christ Church Cathedral, Montreal; biographical sketch by Francis J. Shepherd; Osler's boyhood by a nephew, Dr. Norman Gwyn, Toronto; Montreal days by Dr. A. D. Blackader, Montreal; Osler and the Montreal Veterinary College; a tribute to Sir William Osler by Dr. W. W. Keen; early days at Johns Hopkins Hospital by H. A. Lafleur, Montreal; A

Student's Impression of Osler by W. G. MacCallum; Sir William at Oxford by Archibald Malloch; Sir William and Oxford by two friends; Last Days of Sir William Osler by J. George Adami; The Influence of Sir William Osler on Medicine in America by Thomas McCrae; Osler as Clinician and Teacher by Charles F. Martin; Sir William Osler and the McGill Medical Library by Jean Cameron; Osler's Influence on the Research Student by A. B. MacCallum; The Pathological Collections of the late Sir William Osler and His Relation With the Medical Museum of McGill University by Maude E. Abbott; a Classified Bibliography of Sir William Osler's Canadian Period (1868-1885) by Maude E. Abbott.

REFINED GENEROSITY.

In these days of frequent moving from street to street, from earthly mansions to heavenly mansions, there are always stacks of medical books awaiting a fixed destination by the ignorant women of the household left mourning the doctor, or the hurried decision of a tired man. If worldly wise he will not give first editions, nor the latest. He will not give reprints sent from great men. These are marketable, and besides the medical students of some small town would not appreciate them. So the doctor who is glad to get the credit of being generous and at the same time placate his wife by clearing out those "horrid old books," gathers his second and third editions, his loosely tied up piles of reprints, his volumes by faddists, his piles of journals whose numbers containing valuable articles are missing, and dumps them down in the small library addressed to the resigned, sorrowful librarian who knows their worth before she unpacks them and contemplates a larger laundry bill because of their dustiness. Is this generous?

The same thing is done to medical missionaries. These men often go out from big centres where they had the most recent in medical literature. A generous doctor is asked for books, and, he, regarding missionaries as long bearded old gentlemen raised on the literature of 1850, sends a box which only provokes Christian substitutes for curses. They do not even get any amusement, as the soldiers did when a lady sent in a gift box to the Red Cross with the Dolly Dimple Series and some books on baby treatment for young mothers.

Now how much better if the overbooked doctor would send one or two new editions of well known works, or a goodly pile of reprints with cases, or a year's subscription to a medical society's journal or transactions not usually seen in small libraries. Personally I have always found most generous response to a direct appeal to our leaders in science for their own works, but a circular note is usually handed over to a secretary, only too glad to clear out the shelves. It will require some little thought, some selfdenial to send the book hungry doctor what he needs, but those who have known the pleasant feel of a new book, the certainty of finding what is wanted in it, surely will not again send those bulky, unprofitable selections to their poorer brothers.

News Items.

Cholera in Corea.—Cholera is said to be spreading rapidly in Corea. According to a press dispatch from Seoul, on September 22nd there were 20,000 cases of cholera and more than 9,000 deaths from the disease.

New Medical Publication.—Dr. Piétri, director of the French hospital in Athens, is the editor of a new Greek medical journal, *Iatrikos Typos*, the monthly publication of the French hospital and of the Pasteur Institute of Athens.

German Universities.—A note in the *Paris médical* states that a new university has been established at Cologne, that the University of Bonn has been enlarged, and that new departments have been added in several other German universities.

Pacific Coast Oto-Ophthalmological Society.—The annual meeting of this society was held July 29th and 30th at Portland, Ore. The following officers were elected: President, Dr. George W. Swift, of Seattle; vice-presidents, Dr. E. E. Maxey, Boise, Ida.; Dr. J. O. Chapelle, of Chico, Cal.; secretary-treasurer, Dr. E. E. Wheeler, of Tacoma.

Infantile Paralysis Here.—Following the epidemic of anterior poliomyelitis in Boston and its appearance at other points in the state, the disease has now made its appearance in New York City. Three cases and one death were reported in one day, September 24th. Massachusetts had ninety-four cases in August and 134 during the first twenty-four days of September.

Shanghai Medical School Project Abandoned.—The China Medical Board of the Rockefeller Foundation recently decided to abandon its project for the establishment of a medical school at Shanghai. A reason for this change is the unexpectedly high cost of all the Board's enterprises in China, the Peking Union Medical College having cost larger sums than it had been thought in 1914 would be necessary for both schools. In addition, the capacity of the Peking school has not yet been reached.

Traumatic Neurosis Committee.—A committee has been appointed in England to "consider the different types of hysteria and traumatic neurosis, commonly called 'shell shock' to collate the expert knowledge derived from the service medical authorities and the medical profession from the experience of the war, with a view to recording for future use the ascertained facts as to its origin, nature, and remedial treatment and to advise whether, by military training or education, some scientific method of guarding against its occurrence cannot be devised." Lord Southborough, G. C. B., is chairman.

Institute of Psychology of Paris.—A psychological institute is to be established at the University of Paris associated with the *Facultés des Lettres et des Sciences*. Professors H. Delacrois, G. Dumas, P. Janet, H. Piéron and E. Rabaud will form the council of directors. The institute will undertake the practical and theoretical teaching of all branches of psychology—physiological, experimental, pathological, comparative, and general, and research can be carried out in the laboratories in preparation for university degrees. The diploma course will consist of two terms.

International Institute of Anthropology.—At a meeting held September 9th to 14th in Paris, there was held a conference looking toward the establishment of an international institute of anthropology. A permanent office was created to organize periodical meetings. Subjects taken up at the preliminary meeting were means of organizing inquiries and unification of means of investigation and measurement.

Proposed Coordination of British Hospitals.—The British Red Cross has proposed a plan for coordinating all the hospitals in England and Wales, so that the working population throughout the country may have the benefit of the best possible medical care. It is the object of this projected organization to reduce the expenses and increase the revenue of hospitals. The Red Cross offers to assist voluntary hospitals by affording them the advantages of a big organization, as in some cases their finances do not permit of their making all the necessary modern improvements.

Hoover Seeks Aid for European Children.—The feeding of destitute European children has again become urgent because of inadequate harvests in many countries, and Mr. Herbert Hoover has taken up with various welfare organizations the problem of caring for them. Reports from agents of the American Relief Administration indicate that about two million children in Austria, Czecho-Slovakia, Poland, and Baltic States, and other regions are in need of food and clothing. The American Relief Administration formerly fed six million children, but its funds will be exhausted by January 1st and its chief activities have been turned over to other agencies.

Pathological Congress.—The second international congress of comparative pathology, which was to have taken place in 1914, will be held in Rome in April, 1921, under the presidency of Professor E. Perroncito. The preliminary program announces the subjects for discussion as influenza of man and animals, cancer and sarcoma, rabies and the results of Pasteurian vaccination, plague among ruminants, chicken pest and bee pest, evolutionary cycles of *Dibothriocephalus latus* and *Ascarides*, scabies of man and animals, nerve regeneration, vegetable symbiosis, and parasitism. Pathologists or others wishing to attend should communicate with the general secretary, Professor Mario Levi della Vida, at 58, Viâ Palermo, Rome.

Spanish Antimalaria Campaign.—The League of Red Cross Societies, in agreement with the Spanish Government and the Spanish Red Cross, has decided to undertake an antimalaria campaign in Spain.

The mission which was sent to investigate malaria had as its chief Dr. Massimo Sella, chief of the Department of Malaria of the League. Major Stuart, assistant chief of the Department of Sanitation; Dr. Huntington Williams, of the League staff, and Mr. Juan Larrosa chief of the Spanish section of the Department of Publicity and Publication. At Madrid the mission was joined by Professor Pittaluga, an authority on the subject of malaria. The mission began its work during the first two weeks of August.

American Electrotherapeutic Association.—At the twentieth annual meeting of the American Electrotherapeutic Association, held September 14th to 17th at Atlantic City, the following officers were elected: President, Dr. Byron Sprague Price, of New York; vice-presidents, Dr. V. C. Kinney, of Wellsville, N. Y.; Dr. C. M. Sampson, of St. Joseph, Mo.; Dr. Charles Collins, of Washington, D. C.; Dr. D. A. Cater, of East Orange, N. J.; Dr. W. T. Johnson, of Philadelphia; trustees, Dr. F. B. Granger and Dr. F. H. Morse, of Boston; Dr. W. M. Clark of Philadelphia; Dr. William Martin, of Atlantic City; Dr. Frederic deKraft, Dr. E. C. Titus and Dr. J. W. Travell, of New York; secretary and registrar, Dr. A. Bern Hirsh, of New York.

Local Society Meetings.—The following local Mercy, St. Joseph's, Morrow and University medical societies will meet during the coming week:

Monday, October 4th.—New York German Medical Society.

Tuesday, October 5th.—New York Academy of Medicine (Section in Dermatology and Syphilis), Clinical Society of Harlem Hospital, New York Neurological Society, Society of Alumni of Lebanon Hospital.

Wednesday, October 6th.—New York Academy of Medicine (Section in Historical Medicine), Bronx Medical Association, Harlem Medical Association, Psychiatric Society of New York, New York Urological Society, Society of Alumni of Bellevue Hospital, Brooklyn Society for Neurology.

Thursday, October 7th.—New York Academy of Medicine (stated meeting), Brooklyn Surgical Society.

Friday, October 8th.—New York Academy of Medicine (Section in Otolaryngology), Eastern Medical Society of the City of New York, Flatbush Medical Society.

Saturday, October 9th.—Medical Officers' Reserve Corps Association of the United States Army, New York Division.

Medical Corps Examinations.—Another examination will be held October 25th to 31st, to determine the eligibility for appointment of applicants for the Medical and Dental Corps of the Regular Army. Persons of the following classes who served as officers of the United States Army at some time between April 6, 1917, and June 4, 1920, are eligible to take this second examination:

1. Those who for any good reason did not apply and were not authorized to take the July examinations.
2. Those who were authorized to take the July examinations but who for some good reason were unable to appear before the examining boards.
3. Those who were authorized to take the July examinations and who appeared before examining boards but who for some good reason of their own volition or through illness or accident failed to complete the examination.
4. Those examined during the July examination who were found disqualified on account of physical defects which have been removed by operation or which do not exist at the time of the October 25th examination.

The examination will not be competitive. The number of vacancies in the Medical Corps is sufficient to provide for any reasonable number of applicants who may qualify for appointment. The reference in War Department announcement limiting appointments to be made to 200 does not apply to the Medical Department. As in the past, the military record and general efficiency of the officer will be determining factors for appointment. Candidates must be fifty-eight years of age or under and meet the physical requirements fixed by the War Department. Blank application forms may be obtained from the Adjutant General of the Army or at any military post or station.

Anesthesia Record.—The National Anesthesia Research Society has adopted a uniform chart, which it recommends for use in all hospitals. The committee, consisting of Dr. A. H. Miller, of Providence; Dr. E. I. McKesson, of Toledo, and Dr. A. F. Erdmann, of Brooklyn, studied and compared charts from all leading hospitals and clinics of the United States and the resulting chart is designated to embrace all the essential points in the administration of an anesthetic. The society will print and distribute the chart at cost to all hospitals using it.

Venereal Diseases Conference.—The All-America Conference on Venereal Diseases, to be held December 6th to 11th in Washington, D. C., under the presidency of Dr. William H. Welch, of Johns Hopkins University, is the first of a series of regional conferences suggested by the International Health Conference held at Cannes under the auspices of the League of Red Cross Societies. The administrative committee consists of Dr. Thomas A. Storey, United States Interdepartmental Social Hygiene Board; Dr. C. C. Pierce, United States Public Health Service; Dr. Livingston Farrand, American Red Cross, and Dr. William F. Snow, American Social Hygiene Association. Subjects to be discussed are: Present status and recent progress in medical investigations; education as a means of controlling venereal diseases; law enforcement and protective social measures with individuals; social influence in the control of venereal diseases; administrative measures in the United States, Canada, Latin-America, and other countries. The conference will endeavor to adopt recommendations relating to a practicable three year program for each of the North and South American countries participating and to suggest plans for putting such programs into effect.

Died.

ANDREWS.—In Philadelphia, Pa., on Friday, September 17th, Dr. Reuben H. Andrews, aged seventy years.

BOIES.—In East Aurora, N. Y., on Friday, September 17th, Dr. Loren F. Boies, aged eighty-four years.

BRODNAX.—In Brooklyn, N. Y., on Tuesday, September 21st, Dr. Robert Brodnax.

DILLON.—In Holyoke, Mass., on Sunday, September 12th, Dr. John Aloysius Dillon, aged forty-two years.

JENKINS.—In Saranac Lake, N. Y., on Saturday, September 18th, Dr. Elisha Averett Jenkins, aged forty-six years.

LEFFERTS.—In Katonah, N. Y., on Tuesday, September 21st, Dr. George Morewood Lefferts, aged seventy-four years.

MARSHALL.—In Philadelphia, Pa., on Monday, September 20th, Dr. Anna M. Marshall, aged eighty years.

PAIST.—In Philadelphia, Pa., on Tuesday, September 21st, Dr. Henry Carver Paist, aged eighty-seven years.

STUART.—In Minneapolis, Dr. John Harlan Stuart, aged eighty-four years.

THOMSON.—In Glens Falls, N. Y., on Wednesday, September 15th, Dr. Lemon Thomson, aged sixty-three years.

URQUHART.—In Los Gatos, Cal., on Saturday, September 4th, Dr. Richard Alexander Urquhart, aged seventy years.

VAN DERZEE.—In Dannemora, N. Y., on Thursday, September 16th, Dr. Douw Lansing Van Derzee, aged forty-eight years.

VAN PATTEN.—In Los Angeles, Cal., on Wednesday, September 15th, Dr. Philip S. Van Patten, aged forty-eight years.

Book Reviews

FORESTRY AND HEALTH.

Forests, Woods, and Trees in Relation to Hygiene. By AUGUSTINE HENRY, M. A., F. L. S., M. R. I. A., Professor of Forestry, Royal College of Science, Dublin. Illustrated. New York: E. P. Dutton & Co. Pp. xii-314.

Trees for beauty and tree shade for lovers' meetings, trees for healing, trees to build rough huts and to beautify the inside of palaces; trees to build wave conquering ships and frolicsome canoes; trees to bear men far above the highest mountains in air planes; trees to fashion man's last resting place, his narrow wooden home. Hack at them, make long planks, squeeze out their life blood, take even their dust, and from first to last all in them and of them feeds the ever turning wheel of production and usefulness. The traveler sees the forest crowned hills, the miles of forests, the tiny steamers dragging thousands of tree trunks to the saw mills and thinks, if he thinks at all, that there is plenty of wood in the world.

But war and forest fires, tiny insects and ravaging storms, the greed of man who despoils for the present and plants not for posterity, are making a change in woodlands appreciable even to the thoughtless, and, like the unwise virgins, nation is saying to nation, "Give us of your trees, for ours are few; few, because we recklessly, greedily, consumed our store."

What has Augustine Henry to say? He pleads for the trees, not on the grounds of pure utility, but as hygienists in parks and streets, for water catchment areas, as living green to clothe the hideous pit mounds, as hosts to revivify the tired guest who comes to the sanatorium from hot pavements and miles of houses, as gentle creatures who in new surroundings will find a foothold and do their best to conquer, who will use their old summer clothes to make winter counterpanes for their feet and guard the seedlings of spring beauties from harsh frosts. All this he says of trees in general; he then tells of the various kinds used as healers, where they abound, what they like, where they will thrive and what wonderful guards they will form against sun and wind and raging storm. In studying the influence of forests on temperature it was found that a richly afforested country has a lower temperature in summer, and that the effect of local afforestation is to increase the rainfall. Forests also have a restraining influence on the melting of snow and so retard streamflow at a time when floods are most frequent.

As to the sanitary influence of forests, their advantage in windswept districts is incalculable. The chilly effect of the peat bogs in Ireland and Scotland giving rise to severe spring frosts is well known. Plantations of spruce, maritime pine, Scotch pine and larch would obviate all this. Forests depress the level of the underground water and effectual draining can be done by planting trees, eliminating those marshy places which breed mosquitoes. Napoleon was always ready for suggestion and stayed the malaria in north Africa by those groves of rapidly growing eucalyptus which delight the present residents. But the most important asset is that smoke, dust, injurious gases and

bacteria are rare or absent in the air of forests. Indian villages surrounded by forests are never visited by cholera. The greatest example is that of the Landes in Gascony, once a bare, marshy district subject to malaria and pellagra. Since 1850 some 1,800,000 acres have been planted with maritime pine, and these diseases have practically disappeared.

Good pictures, in print and photos, are given of some of the famous sanatoria, such as Nordrach, Brompton Hospital, Frimlay, etc., dwelling on the effect of trees as wind guards and as forming winter walks but cautioning avoidance of too great crowding near the house itself. He admits the curative effect of the volatile pine oil but says that no scientific studies from a therapeutic point of view, have ever been attempted, Professor Hamburger, of Gröningen University, having gone the furthest.

There is much wise counsel as to town planting, and here he has something to say about desirable aliens. In England, the black walnut and the tulip tree and the *Robinia pseudacacia* are successful, and the London plane (*Platanus acerifolia*) is the street tree which grows best, not only in England, but in Europe and the United States. Birch and poplar grow well in heavy clay soils. Scarcely any conifers succeed in smoky towns, the best being the Austrian and the Corsican pines. He points out that pruning is a surgical operation and a necessity with town trees, therefore advises expert pruners as being more economical in the end.

The afforestation of hideous pitmounds has been triumphantly proved a success. The Black Country in England has some 30,000 acres of pit banks. The psychic effect of so much ugliness is big, but the Midland Reafforesting Association is bigger and much has been done. Best of all, the children have been enlisted and supported by the Forestry Board, so two good ends have been attained. The trees which grow best are the alder, birch and Italian poplar. Lessons are given at the school on rainfall, wind force, frost, drought, geology, fungi, insects, and the parents begin to see there "is something in it." In some parts of France little forestry societies have been founded and flourish finely.

Now comes the biggest part of the subject—the water we drink. The afforestation of water catchment areas is not only a hygienic measure but one to increase the timber reserves. This plan of impounding the water falling on upland and sparsely inhabited tracts is in the category with artificial reservoirs, deriving its supply from drainage of surrounding watersheds. In some cases the land is rented, at others purchased outright. The expediency of keeping it uninhabited is contested by Mr. Hazen, especially with regard to the gathering grounds which supply New York and Boston but Dr. A. C. Houston says this can only be done by storage and filtration if habitation is permitted. Afforestation, not necessarily of the whole area, is the best remedy. Questions of aspect, depth, nature of soil, where and what to plant must be considered. On most catchment areas over 1,000 feet elevation, a combination of grazing and fores-

try must be resorted to. When heavy rain comes, the run off water is much lessened; the quality of the water will be better as the soil on the hill slopes will be held together by the roots of the trees, flood waters will be diminished and the reservoirs not silted up. The careful description of the various suitable trees is a most interesting chapter, the pictures excellent. The records from the catchment areas in the British Isles, though local, contain some valuable points applicable to any towns on any continent. We are grateful to Augustine Henry for introducing us to trees as doctors and rural policemen and are sure that when the book was completed, the trees, as in David's time, "clapped their hands for joy."

HISTORY OF NURSING.

A Short History of Nursing. From the Earliest Times to the Present Day. By LAVINIA L. DOCK, R. N., Secretary, International Council of Nurses, in Collaboration with ISABEL MAITLAND STEWART, A. M., R. N., Assistant Professor, Department of Nursing and Health, Teachers' College, Columbia University, New York. New York: G. P. Putnam's Sons, 1920. Pp. vi-392.

Nurse, nourish, to look after the sick and the well; hospital or zenodochium included inns for the well to do, a hospital for the sick, insane and lepers, asylums for foundlings and orphans, alms houses, houses for doctors and nurses, so here we are traveling round to original meanings. A nurse, no longer one who only attends the sick, but a co-operator in public works to ward off disease, a teacher in health, a hygienist, a panacea, a med-trina all in one. The hospital finds its counterpart in the new Central Health Stations, and the reason they endured, at least the ideal was that they were doing their best to fight disease and misery. Their methods were crude, even smile provoking, but their fight was for the truth and every century sees disease and dirt and miserable housing retreating further and further. It was an international fight, Greeks, Hindus, Egyptians, Romans, the enemy never has been tolerated by them and is now far spent. To open the door to Lavinia Dock and Isabel Stewart is to admit an immense throng of workers of all nationalities, of all creeds, giving up everything to clear the road to health for others. It will be a revelation to the budding nurse who thinks that Eve had a trained nurse when Cain was born and that a Red Cross Unit was attendant at the first battle, to learn how very ignorant, how very narrow minded yet how very advanced were ideas far away back and to find there was always a Nightingale in every age to carol a victory strain and always a body of muddle headed, obstinate men who kick against change as an evil thing.

There is one term which might aptly be applied to the book: that is, thorough. We cannot find any lazy scurrying over important periods because information was difficult to find. It furnishes the nurse with correct information, brightly written, and one volume may tempt readers who, tired with the daily routine of nursing, might shrink from the four vols. of the larger *History of Nursing*, yet it may induce others, hungry for details, to embark on the reading of the four.

The fight is not over: in fact, ammunition is being hurried up by the scientists at such a rate that

the nurse's life will be burdened trying to under-stand its use.

Our hospital system often needs remodeling, our nurses need more humane treatment. No stern abbess or sister of ancient times could draw more tears or make toil more unhappy than many sisters of today. Their glance freezes, their nagging is nerve rasping, their sarcasm is blunt, and their daily visit leaves flushed cheeks and uncomplimentary remarks from the dominated.

TEXTBOOK ON INFECTIOUS DISEASES.

Infectious Diseases. A Practical Textbook. (Oxford Medical Publications.) By CLAUDE BUCHANAN KER, M. D. (Ed.), F. R. C. P. (Ed.), Medical Superintendent, City Hospital, Edinburgh, and Lecturer on Infectious Diseases to the University of Edinburgh; Major, R. A. M. C., T. F. Second Edition. Illustrated. London: Henry Frowde, Hodder & Stoughton (Oxford University Press), 1920. Pp. xii-627.

Writers of medical textbooks seldom succeed in taking their readers to the hospitals, to the beds of patients, and presenting the patients, thus giving practical information concerning the proper classification and treatment of disease. Ker, in the second edition of his book on infectious diseases, has accomplished these things.

He has taken his subject material from the City Hospital in Edinburgh and confined himself to the diseases they handle in that institution, which are in reality the bulk of the infectious diseases encountered in general practice. The diseases he has considered are measles, rubella, scarlet fever, smallpox, vaccinia, chickenpox, typhus fever, enteric fever (known in America as typhoid fever), diphtheria, erysipelas, whooping cough, mumps, and cerebrospinal meningitis. Throughout the book Ker has dwelt at great length on the important subjects of diagnosis, prognosis, and treatment. Various theoretical phases of the various diseases are carefully avoided. The aim throughout the book has been to make it useful to the practitioner; useful in an immediate practical way and not in an abstract fashion. The portion of the book dealing with typhoid fever is a most excellent monograph when taken separately. The general tone of the book is not one of uncertainty; the subjects are presented with clarity and directness. The arrangement of the book makes the various sections easily available for quick reference.

BEAUTY.

The Substance of a Dream. Translated from the Original Manuscript by F. W. BAIN. Illustrated. New York: G. P. Putnam's Sons, 1920. Pp. iii-216.

From India, the mystic land of legends and cults founded on phantasy, we have had much that is beautiful. Centuries of grappling with the unknown; an endeavor to create beauty to compensate for crushing circumstances and a soaring in worlds of wonder; countless centuries of silent suffering have led to an acceptance of things as they are. Yet the stoic exterior covered a nimble brain that was creating spirals in an effort to make up for the things that had been deprived. They decorated their temples with the spirals and wove them into the tracery of their stories. They spent little time in portraying reality, for they were surrounded by too much reality and a reality that was too sordid;

they did not have the physical nor the psychic courage to combat the forces which they felt were stronger than any powers they could create from their own ego. Some say there is an awakening today—who can tell. We shall not go into that; we shall only consider some of the products of the day before, when they found their outlet not in trying to better their condition materially but created one in their mind and retreated to the beauties of their own making.

The *Substance of a Dream* is the latest of a series of translations from the original Sanscrit by Bain. These stories sing with a melodious beauty, for they have been retold by a man who felt joy in the telling. The tale is one of love and the pitfalls encountered. Here, as in affairs less emotional, pitfalls and difficulties are encountered along the road and at the turnings. Frequently we recognize our own excursions, though they would require an elastic transformation to the realm of phantasy to cope with the heroic outlines cast by the shadow of the Hindoo participants. But why dwell upon this, for in every story obstacles of one kind or another are encountered. This is as it should be—for the convenience of the tale-teller. It is not here that he quarrels with reality but only in the solution of the difficulties.

One of the dominant notes of the Bain translations, and we may infer that they reflect much Hindoo philosophy, is the rebirth phantasy. Here the great retreat is found. Back to the day of infantile pleasure unmarred by unbending reality. Another chance is called for and the easiest way to realize it, in imagination, is the phantasy of a rebirth. These stories reveal the psychological reaction of a people long held in a bondage of soul and body. And we find the reactions not unlike those of other peoples under similar circumstances. The difficulties found in their love life will be reduplicated and met in the same way in all of the less beautiful phases of life. The stories are of the beautiful and are beautifully told.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE THEORY AND PRACTICE OF MASSAGE. By BEATRICE M. GOODALL-COPESTAKE, Examiner to the Incorporated Society of Trained Masseuses; Teacher of Massage and Swedish Remedial Exercises to the Nursing Staff of the London Hospital. Second Edition. Illustrated. New York: Paul B. Hoeber, 1919. Pp. xxi-265.

THE DIAGNOSIS AND TREATMENT OF HEART DISEASE. Practical Points for Students and Practitioners. By E. M. BROCKBANK, M.D. (Vict.), F.R.C.P., Hon. Physician, Royal Infirmary, Manchester; Lecturer in Clinical Medicine, Dean of Clinical Instruction, University of Manchester. Fourth Edition. Illustrated. New York: Paul B. Hoeber. Pp. viii-158.

THE X RAY ATLAS OF THE SYSTEMIC ARTERIES OF THE BODY. By H. C. ORRIN, O. B. E., F. R. C. S., Ed., Fellow of Royal Society of Medicine, London; Civil Surgeon Attached 3rd London General Hospital, R. A. M. C. (T.). Illustrated. New York: William Wood & Co., 1920. Pp. i-91.

FEMINISM AND SEX EXTINCTION. By ARABELLA KEANEALY, L.R.C.P. (Dublin). New York: E. P. Dutton & Co. Pp. x-313.

TRANSACTIONS OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION. For the Year 1918. Volume xxxiv. Lancaster, Pa. The New Era Printing Co., 1918. Pp. v-294.

THE NEW PSYCHOLOGY AND ITS RELATION TO LIFE. By A. G. TANSLEY. Illustrated. New York: Dodd, Mead & Co. (London: George Allen & Unwin, Ltd.). Pp. v-283.

FORTY-SEVENTH ANNUAL REPORT OF THE COMMISSIONER OF THE MICHIGAN DEPARTMENT OF HEALTH FOR THE FISCAL YEAR ENDING JUNE 30, 1919. Fort Wayne, Indiana, 1920. Pp. 5-196.

LA CURE DE DIURÈSE. Par le Docteur CHARLES RICARD POMARÈDE, Lauréate de Faculté de Médecin, Ex-Interne P. des Hôpitaux de Montpellier, etc. Paris: J. B. Ballière et Fils, 1920. Pp. vii-88.

STUDIES IN NEUROLOGY. By HENRY HEAD, M.D., F.R.S., in conjunction with W. H. R. RIVERS, M.D., F.R.S., GORDON HOLMES, M.D., C.M.G., and several others. In Two Volumes. London: Henry Frowde (Oxford University Press), and Hodder & Stoughton, Ltd., 1920. Pp. ix-862.

HANDBOOK OF DISEASES OF THE NOSE, THROAT, AND EAR. For Students and Practitioners. By W. S. SYME, M. D., F. R. F. P. and S. G., F. R. S. E., Surgeon to the Ear, Nose and Throat Hospital, Glasgow; Extra-Academical Lecturer on Disease of the Throat and Nose, Glasgow University, etc. Illustrated. New York: William Wood & Sons, 1920. (Edinburgh: E. & S. Livingstone.) Pp. viii-329.

A SHORT HISTORY OF NURSING. FROM THE EARLIEST TIMES TO THE PRESENT DAY. By LAVINIA L. DOCK, R. N., Secretary, International Council of Nurses. In Collaboration with ISABEL MAITLAND STEWART, A. M., R. N., Assistant Professor, Department of Nursing and Health, Teachers College, Columbia University, N. Y. New York: G. P. Putnam's Sons, 1920. Pp. vi-392.

INFECTIOUS DISEASES. A Practical Textbook. (Oxford Medical Publications). By CLAUDE BUCHANAN KER, M.D., Ed., F.R.C.P., Edin., Medical Superintendent, City Hospital, Edinburgh, and Lecturer on Infectious Diseases to the University of Edinburgh, Major, R.A.M.C., T.F. Second Edition. Illustrated. London: Henry Frowde (Oxford University Press), and Hodder & Stoughton, 1920. Pp. xii-627.

THE OXFORD MEDICINE. By Various Authors. Edited by HENRY A. CHRISTIAN, A.M., M.D., Hersey Professor of the Theory and Practice of Physic, Harvard University, Physician in Chief to the Peter Bent Brigham Hospital, Boston, Mass., and SIR JAMES MACKENZIE, M.D., F.R.C.P., LL.D., F.R.S., Consulting Physician to the London Hospital, and Director of the Clinical Institute, St. Andrews, Scotland. In Five Volumes. Illustrated. New York and London: Oxford University Press. Pp. xxiii-923.

MASSAGE AND EXERCISES COMBINED. A Permanent Physical Culture Course for Men, Women, and Children. Health Giving, Vitalizing, Prophylactic, Beautifying. A New System of the Characteristic Essentials of Gymnastic and Indian Yogis Concentration Exercises Combined with Scientific Massage Movements. With eighty-six Illustrations and Deep Breathing Exercises. By ALBRECHT JENSEN, Formerly in Charge of Medical Massage Clinics at Polyclinic Hospital and Other Hospitals, New York. New York: Published by the Author, 1920. Pp. 13-93.

PLASTIC SURGERY OF THE FACE. Based on selected cases of War Injuries of the Face Including Burns. With Original Illustrations. By H. D. GILLIES, C.B.E., F.R.C.S., Major, R. A. M. C., Surgical Specialist to the Queen's Hospital, Sidcup Surgeon in Charge of the Department for Plastic Surgery, and Late Surgeon in Charge of the Ear, Nose and Throat Department, Prince of Wales Hospital, Tottenham, etc. With Chapter on The Prosthetic Problems of Plastic Surgery, by Captain W. KELSEY FRY, M.C., R.A.M.C., Senior Dental Surgeon, Queen's Hospital, etc. Remarks on Anesthesia, by Captain R. WADE, R.A.M.C., Late Senior Anesthetist, Queen's Hospital, etc. London: Henry Frowde, (Oxford University Press) and Hodder and Stoughton, 1920. Pp. xiii-408.

Practical Therapeutics and Preventive Medicine

A Compendium of Treatment and Prophylaxis, Original and Adapted

Secondary Syphilis of the Heart.—C. Oddo and C. Mattei (*Bulletin de l'Académie de médecine*, March 30, 1920) believe the heart to be much more frequently involved in the secondary stage of syphilis than is generally thought. They report a case of syphilitic pericarditis and rapid heart failure in a patient aged fifty-four years with mucous patches of the labial commissures and scrotum. The heart improved slightly under mercury cyanide and novarsenobenzol injections—though refractory to digitalis—but on the day of the last injection pulmonary edema developed and death followed. The autopsy showed marked pericardial disease but no involvement of the myocardium nor endocardium. Cases already recorded show that mild secondary syphilitic involvement of the heart may be manifested merely in arrhythmia, and more severe involvement, in more or less pronounced heart weakness or failure. The diagnosis is based on the history and clinical course of the case, the Wassermann reaction, and especially, the therapeutic test. Cardiac disturbance should be carefully watched for in secondary syphilis, and syphilis should be thought of in all cases of rapid heart enfeeblement without known cause. The prognosis should be as guarded as that of definite syphilitic meningitis in the secondary stage. Antisyphilitic treatment, after preparatory measures similar to those preceding digitalis administration, is of greater service than the usual heart tonics. Mercury seems to be the remedy of choice. Arsphenamine should be used with caution as it may favor dangerous heart collapse and pulmonary edema.

Influence of Insufficient Treatment upon the Appearance of Meningeal Syphilis.—Marcel Pinaré (*Paris médical*, March 6, 1920) asserts that either insufficient or active antisyphilitic treatment may favor syphilitic involvement of the nervous system. In such cases an active drug has been given in insufficient doses, in unduly brief courses, or with undue intervals between successive courses. The treatment has been active enough to prevent the appearance of skin lesions, but the spirochetes have migrated to the nervous system, where they are less vulnerable. This accounts for the numerous nervous disturbances, deafness, ocular paralyses, etc., noted during the earlier trials of arsphenamine, especially during the period in which, owing to fear of untoward happenings, the doses were reduced. Nicolau, among fifty-one patients with chancres, found a spinal lymphocytosis in eighteen. When these cases were given twenty injections of 0.02 gram of mercury biniodide, the lymphocytosis, instead of diminishing, nearly always increased. The author observed similar effects in the treatment of nervous syphilis with arsenicals. Often there is aggravation of the clinical manifestations and increase of spinal lymphocytosis after the first series of arsphenamine injections. One of the cases mentioned showed that even an intensive treatment might be insufficient, in spite of the administration

of 5.25 grams of neoarsphenamine; the difficulty in this case was that the maximum doses of 0.9 or 1.05 grams were not reached and that the first series of injections was not followed up by further series. Therapeutic neurotropism may occur alike after mercurial or arsenical treatment. The essential point is that the compounds that are only moderately active, such as the benzoate or biniodide of mercury and mercurial pills are dangerous; likewise, small doses of highly active preparations are dangerous, and single series of treatments or treatments at excessive intervals with the highly active preparations are dangerous. At the onset of syphilis the treatment given should be intensive and the drugs used administered in actually spirocheticide doses. After the initial treatment, the period of rest should be short. Treatment should be kept up to the point of disappearance of the clinical, serological, and cerebrospinal signs. The least nervous reaction indicates intensive treatment. Intense and continuous treatment of syphilis during the first few weeks of the infection affords some chances of complete cure. On the other hand, faulty management at the outset may, as in one of the cases reported, result in the development of lesions removable only with difficulty, even by prolonged treatment.

A Comparative Study of the Trypanocidal Activity of Arsphenamine and Neoarsphenamine.—Jay F. Schamberg, John A. Kolmer, and George W. Raiziss (*American Journal of the Medical Sciences*, July, 1920), say that trypanocidal tests employing rats infected with *Trypanosoma equiperdum* provide a means for determining the curative properties of arsphenamine and neoarsphenamine. Medicinals which prove trypanocidal *in vivo* are probably curative in syphilis; other compounds, such as the mercurials, which are unable to influence experimental trypanosomiasis, may still influence infections with *Trypanosoma pallida*; such tests possess, therefore, a greater positive than negative value in chemotherapeutic studies in syphilis. In conducting such tests the virulence of the strain, the method of infection, the interval between infection and treatment, and the weight of the test animals are modifying factors and must be rendered uniform to secure satisfactory results. With the strain of *Trypanosoma equiperdum* employed in the experiments described, the smallest amounts of arsphenamine sterilizing rats infected twenty-four hours previously varied from 0.010 to 0.030 gram to the kilo of body weight, the average being 0.023 gram to the kilo of rat. The smallest sterilizing doses of neoarsphenamine under identical conditions varies from 0.020 to more than 0.040 gram to the kilo of rat; average about 0.040 gram to the kilo. The trypanocidal activity of different lots of arsphenamine and neoarsphenamine prepared by the same laboratory and by different laboratories varied in a manner analogous to variations in lethal toxicity for rats. The trypanocidal activity of arsphenamine is 1.74 times greater than that of

nearsphenamine, and 0.6 gram arsphenamine equals 1.05 rather than 0.9 grams of nearsphenamine in therapeutic activity. The trypanocidal dose of arsphenamine is 4.56 times less the highest tolerated dose for the rat; that of nearsphenamine is 6.35 times less the highest tolerated dose. These results indicate that nearsphenamine is a somewhat safer compound than arsphenamine; even when one gram of the former is administered as equivalent in therapeutic activity to 0.6 gram arsphenamine, the margin of safety is greater.

Comparative Studies of the Toxicity of Arsphenamine and Nearsphenamine.—Jay F. Schamberg, John A. Kolmer, and George W. Raiziss (*American Journal of the Medical Sciences*, August, 1920) say that in so far as the toxicity of arsphenamine and nearsphenamine may be determined by intravenous injection of solutions in rats, the single dose of arsphenamine commonly administered (0.6 gram) may be said to be about one twelfth the highest tolerated dose, and the highest single dose of nearsphenamine commonly injected (0.9 gram) is about one nineteenth that of the tolerated dose. From the viewpoint of the margin of safety larger amounts of nearsphenamine may be given and maintain the same ratio between the therapeutic and the tolerated dose as apparently exists with arsphenamine.

Relapses After Prostatectomy.—Victor Blum (*Urologic and Cutaneous Review*, May, 1920) mentions the following possibilities in recurrence after prostatectomy: 1, Carcinomatous relapse, either as a local recurrence after extirpation of a carcinomatous prostate, or as a carcinomatous degeneration of the site of operation or of the scar after removal of an apparently benign tumor, but in reality one undergoing malignant change; 2, recurrence due to an incompletely performed prostatectomy, that is, in place of a total or subtotal prostatectomy, an incomplete operation; 3, recurrence in consequence of cyst formation in the *loge prostatique*—an observation made by Papin, cited by Nogues; 4, recurrence due to new formation of glandular tissues.

Treatment of Syphilis.—F. W. Cregor (*Journal of the Indiana State Medical Association*), in discussing the method of treating syphilis practised in United States Public Health Service Clinics of Indiana, emphasizes the following points: 1. The medical profession should take an uncompromising stand for the full and complete treatment of syphilis. 2. This can best be done by full cooperation with the lawfully constituted health organizations of the country. 3. Syphilis may be aborted if encountered before five weeks have elapsed from the contraction of the disease. 4. Syphilis may be cured by one year of treatment, providing it is encountered before it has found lodgment in the tissues of the host. 5. Syphilitics may be assured that they will remain free of symptoms, providing they fully cooperate in the treatment. 6. The Wassermann test should be employed as an aid and a comfort, and not as a guide and a control for action. 7. As full cooperation is impossible in the face of ignorance of the disease and its potentialities, it is necessary that the patient be apprised fully and honest-

ly of these things. 8. Steps should be taken to reclaim the neurosyphilitic, possibly through the insane institutions, until such time as public enlightenment will relieve the present demand. 9. A spinal Wassermann test should be made in all cases before the patient is discharged.

Hereditary Syphilis and Dystrophies.—P. Huttel (*Archives de médecine des enfants*, January, February, March, and April, 1920) divides the lesions dependent upon hereditary syphilis into two groups, those containing specific, localized alterations, such as treponema, and those involving nutritional difficulties producing dystrophies. Most of the stigmata of the disease are found among the dystrophies. Stigmata are usually multiple, such as deformities of the skull, the nose, the teeth, alteration of the cornea, the ear, the testicles, etc. There may also be visceral scleroses. These are the local dystrophies. The general dystrophies interfere with the development of all parts of the same apparatus. They are usually indicated by nutritional difficulties, often involving the nutritive agency of the endocrine glands. When the nutritional difficulties, imputable to glandular or organic lesions, have been caused by hereditary syphilis or by some other morbid processes, they may be transmitted from parents to children. Specific medication becomes less important as the dystrophies caused by hereditary syphilis draw away from their infectious origin. Qpotherapeutic medication is, however, increasingly indicated as the infection recedes.

Significance of Syphilis in Prenatal Care and in the Causation of Fetal Death.—J. Whitridge Williams (*Bulletin of the Johns Hopkins Hospital*, May, 1920) bases the present study on 302 fetal deaths occurring in 4,000 consecutive deliveries between April, 1916, and December, 1919. In each case a Wassermann test was made and if the result was positive the patient was given treatment provided sufficient time was available before delivery; 1,839 of the patients were white, and 2,161 were colored women. The Wassermann reaction was positive in 2.48 per cent. of the white patients and in 16.29 per cent. of the blacks. Autopsies were performed on 212 of the 302 dead babies. In these figures are included not only those dying at the time of labor or during the two weeks immediately following it, but also those dying during pregnancy from the time of viability onward. Ninety-nine of the 302 deaths occurred in white and 203 in black infants, while 157 occurred at the time of labor or during the first two weeks of the puerperium, and 145 were in premature children. Syphilis was noted in 104 cases, in 89 of which the diagnosis was confirmed at autopsy by the demonstration of spirochetes; in the rest it was made on the presence of syphilitic lesions in the placenta, associated with a positive Wassermann in the mother. Syphilis was responsible for 34.44 per cent. of the total number of deaths in this group of cases. In the patients where syphilis was recognized early in pregnancy and appropriate and efficient treatment was given, hopeful results were obtained, so that if women register prior to the middle of pregnancy in properly conducted clinics syphilis may be practically eradicated as the cause of fetal death.

Sodium Taurocholate in the Prophylaxis of Gonorrhoea.—L. Cheinisse (*Presse médicale*, February, 14, 1920) notes that Aldo Castellani has found that bile and bile salts prevent the development of the gonococcus *in vitro* and has recommended the local use of a solution of two to four grams of sodium taurocholate in thirty grams of pure glycerine as a gonorrhoea prophylactic. A few drops of this solution are dropped in the meatus, held open for the purpose, and over the glans and the balanopreputial sulcus, before coitus. Later the organ is washed and the prophylactic local medication repeated. Some of the solution may be instilled with a small syringe. In one clinical experiment, fresh gonorrhoeal pus containing many gonococci was mixed for three minutes with the sodium taurocholate solution and introduced into the healthy meatus. In another, a few drops of the remedy were introduced into the meatus, followed, three minutes later, by gonorrhoeal pus; after five minutes, the subject urinated, washed the organ with soap and water, and introduced a few more drops of the taurocholate solution. Neither of these subjects contracted gonorrhoea. The preparation is considered advantageous in being easily prepared, inexpensive, requiring no apparatus for its employment, and in causing no local burning or pain.

Removing Ureteral Calculi Without Operation.

—A. J. Crowell and Raymond Thompson (*Southern Medical Journal*, June, 1920) reported in August, 1918, the successful application of the method given below in twenty-nine out of thirty-one cases of urethral stone, and since then have been successful in twenty-five other cases. A bismuth catheter is inserted into the ureter until it meets with obstruction. An x ray picture is taken to demonstrate that the obstruction is stone, as well as to ascertain its size and location. No obstruction should be diagnosed as stone unless it is shown in the picture or is recovered, as the symptoms of stone may be simulated by ureteritis, ureteral stricture, kink, or pressure on the ureter. Two c. c. of a two per cent. solution of cocaine or procaine is slowly injected into the ureter at the site of impaction. The ureteral spasm is so relaxed in a few moments that the catheter will usually pass beyond the stone, where another c. c. or two of the anesthetic is injected further to deaden the sensation. At this point it is well to distend the kidney pelvis with a physiological salt solution and inject sterile olive oil as the catheter is being removed. In this way the pressure above the stone is increased and assists in expelling it, while the muscular fibres of the ureter are relaxed and the sensation is deadened. If we fail to get the eye of the catheter above the stone, sterile oil is injected against it with considerable force in an endeavor to dislodge it as well as to lubricate the parts and dilate the ureter below the obstruction. The patient is given morphine and instructed to drink water freely. This technic is repeated every second or third day, increasing the size of the ureteral catheter each treatment. Quite frequently a No. 11 stoppered catheter is inserted and left *in situ* for hours. This is especially beneficial where it is impossible to get past the stone and the obstruction to the secretion is incomplete.

Precocious Malignant Syphilis.—Queyrat and Mouquin (*Presse médicale*, January 31, 1920) report the case of a woman suffering from primary malignant syphilis, with fever and poor general condition. The Bordet-Wassermann reaction was partially positive. No spirochetes could be found, but under injections of novarsenobenzol the lesions underwent prompt retrogression, the temperature receded and the general condition improved. The writers make a distinction between severe syphilis and precocious malignant syphilis; in the former the spirochete is generally found, but in the latter it is wanting. The condition is a special morbid entity beginning with a chancre, often of ulcerative type. There was no mucous patches and no roseola. Lesions of different age are found on the patient at the same time, viz., papules, vesicopustules, and crusted and ulcerous lesions. The Wassermann remains negative at first, becoming positive two or three months after the start of the infection. The various mercurials and potassium iodide are generally insufficient to remove the manifestations of the disease. Arsenobenzol, on the other hand, is very efficacious. The etiology of this precociously malignant form of syphilis remains obscure. It does not seem possible to ascribe it to the general condition of the patient, for the disease occurs in robust individuals. Possibly a special strain of spirochete is responsible for it.

Diagnosis and Treatment of Luetic Involvement of the Optic Pathways.—Mark J. Schoenberg (*Archives of Ophthalmology*, March, 1920)

says that although our present means of establishing a diagnosis constitute a pretty good armamentarium to furnish more or less satisfactory information, early diagnosis of syphilis of the optic pathways is not made except in an infinitesimal percentage of cases. He asserts that examinations should be begun as soon as the primary lesion makes its appearance and repeated at regular intervals during the entire time the patient is under the observation of the physician. Diagnosis must be accurate, and one of the most difficult problems is the diagnosis of a nonsyphilitic condition in a patient with syphilis. There are many pitfalls, of which he considers the first and most dangerous to be the Wassermann blood test. It has almost become an established tradition that a patient with an optic neuritis or an optic atrophy, and a three or four plus Wassermann blood reaction, must have a syphilitic optic nerve lesion, yet nothing may be further from the truth. A single blood test can never be depended on for a final decision. The condition may be due to a cause other than syphilis, though the patient be syphilitic, or it may be due to syphilis plus one or several other causes. Conditions to be borne in mind while investigating such cases include, first, acute or chronic sepsis from foci of infection in nasal sinuses, tonsils, teeth, gallbladder, appendix, genitals, and intestines; second, acute or chronic toxemias, lead, arsenic, alcohol and disturbances of digestion, nutrition, elimination, and the endocrine system; third, acute or chronic trauma, emotional, physical, occupational, such as aneurysms, empyema of the nasal sinuses, periostitis of the optic foramen; and fourth, heredity and congenital conditions. One

of the most valuable additions to our diagnostic armamentarium of late years is the examination of the spinal fluid. The information we obtain shows us whether we have to deal with a luetic involvement of the central nervous system; gives a clue as to about what pathological type of lesion of the optic path we are dealing with, and furnishes us a good deal of information about the prognosis. Concerning the disagreement of opinion regarding the indications and efficacy of intraspinal and intracranial medication, he thinks that the good results obtained are due not so much to the medication as to the meningeal reaction, the active hyperemia.

After a diagnosis has been made we must ascertain whether there is yet present an active process. End results of a condition which has come to a standstill need no treatment. A partial optic atrophy with no tendency to progress, with negative findings in the blood and spinal fluid, and no clinical evidence of an active neurological disease, should be watched but not treated. For patients with vision reduced to counting fingers at a few feet, poor fields and atrophic discs, there is not much hope. There remains the group of cases with 20/200 vision or more, with fairly good fields, and in good general condition, to be treated according to the type of neurolyues and type of optic nerve lesion present. Therapeutically it is of the greatest importance to have a clear idea of whether we have to deal with taboparesis, cerebrospinal lues, or a vascular case; what type of optic pathway lesion the patient has, and in what stage of lues the optic pathway became involved. The indications, the dose, the frequency of treatments, and the method of administration are quite different, not only in each type of neurolyues, but also in each type of optic path syphilis. It is therapeutically meaningless to say optic atrophy, without mentioning the kind of atrophy we are dealing with.

Treatment of Varicose Ulcers, Chronic Metritis, and Chancroid with the Salts of Rare Earth Metals.—Albert Frouin (*Bulletin de l'Académie de médecine*, April 6, 1920) asserts that salts of the rare earth metals, and in particular the sulphates of the cerium group, which are less irritating than the nitrates and chlorides, possess antiseptic properties. Two to four per cent. solutions of these salts promote the healing of wounds, and favor the formation of the dermis and of the epithelial layers. In war practice good results were obtained in atonic wounds that had already been suppurating for prolonged periods. One patient had been in a hospital eighteen months with a large burn of the scalp in the occipital region. Suppuration was very marked and showed both the staphylococcus, streptococcus, and pyocyanus; grafting had already been tried without success. Later another graft was applied and covered with dressings of two per cent. lanthanum sulphate solution. Six weeks later the wound had almost completely closed. In four cases of long standing varicose ulcer, moist dressings of rare earth salts twice daily brought about healing in twenty to thirty-three days. In thirty-four patients with ulcers of the cervix or chronic metritis tam-

ons impregnated with solutions of rare earth salts were used twice weekly. In some instances an iodine compound was applied for a short time before introduction of the tampons. As a result, pain and dragging sensations were relieved, discharge ceased, and healing took place in four to twelve weeks or, in five patients in whom daily treatment could be given, in fifteen to twenty-two days. In a case of chancroid of the fourchette, insertion two or three times a day of a tampon impregnated with lanthanum sulphate solution, together with special treatments twice a week, was followed by recovery in seven days. Guénot, in a number of cases of chancroid in men, treated with two to four per cent. solutions of lanthanum sulphate, obtained recovery in from seven to twenty days.

Effects of Mercury Salicylate on the Wassermann Reaction.—Herman Goodman (*Archives of Dermatology and Syphilology*, August, 1920), presents his observations on the results of serological treatment in previously untreated syphilitic men. He states that eighty-seven of these men, with four plus Wassermann reactions, were given one grain of mercury salicylate intramuscularly at weekly intervals for courses of from six to eight injections. The Wassermann reaction, immediately after treatment, remained strongly positive in sixty-six per cent. of the cases. In only nine per cent. was there a reversal to negative; and in some of the patients, who were given a third Wassermann test after an interval without treatment, the reaction was positive. It seems fair to conclude, with Anderson and Nelson who carried on a similar study in 1915, that mercury salicylate alone and for the period given does not qualify as a curative agent in syphilis. The plans for a longer study were curtailed by the demobilization. In the future mercury salicylate will be used in increasing doses up to two and two and a half grains weekly.

Tests of Renal Function.—C. W. Dowden (*Southern Medical Journal*, May, 1920), in presenting a comparison of a few of the simpler tests with the more elaborate ones, states that in his opinion practically as many facts can be obtained by a careful examination of the urine at each voiding, regardless of time and covering a period of three days or longer, during which only capacity diet is insisted upon, especially in the quantity of the night urine and the fixation of specific gravity at a high or low level, as can be obtained by the more elaborate methods. Comparing the daily output with the intake offers not only valuable diagnostic evidence, but is a most helpful index for proper treatment. He has seen marked improvement in chronic nephritis by limiting the intake of fluids to not more than 400 c. c. in excess of the previous day's output. Blood pressure (except in the arteriosclerotic) usually declines promptly, and when there is close agreement in intake and output there is always noticeable a marked improvement in the patient's general condition. He is firmly convinced that the indiscriminate advice to nephritics to drink an abundance of water is wrong and probably as dangerous as to advise them to eat plenty of meat and salt. In chronic nephritis the salt output is disturbed little or not at all.

Proceedings of National and Local Societies

SOCIETY FOR THE PREVENTION OF VENEREAL DISEASE.

*First Annual General Meeting held in London, on
Thursday, June 3, 1920.*

LORD WILLOUGHBY DE BROKE, President of the Society, in
the Chair.

President's Address.—LORD WILLOUGHBY DE BROKE said that the origin of this society was a certain White Paper which was published by the Government some months ago setting forth the official view with regard to what was then called prophylaxis in relation to the treatment of venereal disease. That White Paper was issued as an account of the deliberations of an Interdepartmental Committee appointed for the purpose of inquiring into the subject. The whole purport of the report and the whole complexion of the official point of view was against the policy of immediate self-disinfection as a prophylaxis against venereal disease, which had undoubtedly been proved to have been a success. No disease had ever been stamped out merely by trying to heal the symptoms, unless the healing had been accompanied by the most scientific methods of prevention. The prevention of venereal disease was of two kinds: moral prevention, and second, abstinence from promiscuous intercourse. All that was very good and should be advocated on every possible occasion, but the common sense of the thing was that if you wished to avoid contagion you should avoid contact. It was equally true that in spite of all the exhortation and in spite of the fact that the nation—and in particular the army—had been lectured over and over again with regard to the dangers of promiscuous intercourse, venereal infection was still proceeding at an alarming rate; moral prevention, although an excellent thing so far as it went, had hitherto failed to achieve the object of stamping out or even of lessening the incidence of the disease.

There remained medical prevention of two kinds, delayed or immediate. The official policy was that of delayed disinfection which it was proposed to carry out at ablution centres where those who had been incontinent should be treated by a skilled attendant. If people were to know where they were, these ablution centres must be made conspicuous. But if they were made sufficiently conspicuous to attract attention they would be so conspicuous that no person would care to be seen entering an establishment of that kind. Nothing was more grotesque or more liable to incite the blackmailer and the spy than an ablution centre in a rural village. So much for delayed disinfection. Therefore, it remained to consider the other policy, which was the primary policy of this society, that was the policy of immediate self-disinfection applied by the man or the woman within a few seconds after coition had taken place. The Government thought this would make promiscuous intercourse between the sexes too easy and would deliberately invite people to indulge in it. That was a low estimate to

form of the morality of one's fellow countrymen, and if venereal disease was only kept in check by fear of the consequences, he was afraid fear had not been a very successful agent in stamping out promiscuous intercourse between the sexes. The only safe, the only wise, the only human, the only statesmanlike course was to recognize the fact that in spite of all this preaching and lecturing and incitement to lead a healthy life, we had at present failed to suppress the sexual instinct to such a degree as to have any effect upon the incidence of venereal disease. Therefore, if you were to attack venereal disease, you must attack it at the weakest link, and the weakest link in the chain of infection was immediately after the connection had taken place. Hence the whole aim and object of this society was to urge the Government to bring pressure on all public bodies to issue such instructions to our fellow countrymen and countrywomen as would enable them to take advantage of the latest teachings of science, in order that they might themselves use immediately after connection, if connection there must be, such ample disinfectants as were known to be efficacious in destroying immediately the spirochete and the gonococcus.

The highest moral attitude that the State could adopt was the health of the citizens, and we would not be responsible to future generations for our having suppressed knowledge which, if intelligently applied, might well prevent thousands of them from hideous sufferings in the future. Only one obstacle which stood in the way of the adoption of that policy and that obstacle was contained in a certain clause in the Venereal Disease Act of 1917, the gist of which was that no person should hold out or recommend to the public any notice or advertisement of anything for the prevention, cure or relief of any venereal disease. In order to test this the speaker went to a well known chemist in the West End of London and asked him whether he could supply some calomel cream ointment, thirty-three per cent., and a solution of one in a thousand of potassium permanganate, and he said yes. If he had come into the shop and asked for these things with a view to averting venereal disease the chemist said he could not legally supply them. Inasmuch as a little unscientific knowledge was dangerous in the highest degree, it was important that knowledge should be made available to the public under the control and with the supervision of qualified medical authorities, such as the Ministry of Health, medical officers of health all over the country, or the local government board. It was to that policy that he invited cooperation, he therefore asked votes for this resolution:

Resolved, That inasmuch as the Ministry of Health had failed, and public bodies, including the London County Council, have declined to provide the means of delayed disinfection against venereal disease at ablution centres, this meeting calls upon the Ministry of Health and upon local authorities to instruct all qualified chemists to sell such means of immediate self-disinfection against venereal disease as may be approved from time to time by the Ministry of Health or by medical officers of health.

DR. C. W. SALEEBY, F. R. S. E., said that it was astonishing that those who were now opposed to us had themselves connived at the confusion between prevention and treatment which we desired put an end to. When attempts were made in the army to deal with the disease by means of disinfection, those attempts were labeled early treatment, and by those who labeled disinfection early treatment we are now told that a policy of disinfection would lead to the belief that disinfectants could be used for treatment. That was not our fault; it was the fault of those who did not have the common honesty to label disinfectants as such, but called them early treatment, which they were not, and could not be. The resolution which Lord Willoughby de Broke had proposed drew attention to the fact that at this moment there was no effective work being done against the spread of venereal disease in this country. The great obstacle in the way of making progress was the Ministry which had been largely created for the purpose of dealing with venereal disease. He drew attention to the fact that there had just been published the report of the National Birthrate Commission, a body which devoted a great deal of attention to this subject. In the last two years they heard evidence from Sir William Osler, Sir Bryan Donkin, and Mr. E. B. Turner, a body which comprised a number of women, a minority of whom were scientific, and which was presided over by the Bishop of Birmingham. The National Birthrate Commission recognized that no difficulty of an official kind should be placed in the way of obtaining disinfectants by individuals for use after exposure.

Sir JAMES CRICHTON-BROWNE, F. R. S., said the society had every reason to be grateful to the people of the country for the support and the encouragement it had received, but it had a great task, and if it was to perform that task properly it must appeal for help and support, and he would particularly bring this home to the employers of labor. In the *Times* this morning there was a letter from Mr. Hyndman pointing out that the rats were at this moment consuming grain to the value of £45,000,000 annually. There was another kind of vermin, a much smaller kind, the spirochete, which was responsible for syphilis that was costing the country hundreds of millions per annum, and it would be a great economy on the part of the government if it would place in our hands £100,000 at this moment to carry out a complete and efficient propaganda throughout the whole country. It would result immediately in the saving of millions. They should remember that 20,000 infants were destroyed by syphilis before birth; all through childhood it was carrying off promising children; it was rendering fruitful women barren, and if we could only obtain an accurate account of its effect on labor, and the number of day's labor that were lost by men suffering from syphilis and whose productivity afterward was reduced by poor health, we should have a most startling return. That was what this disease was costing the country.

He would urge the employers of labor to come to us, to invite us to provide lectures for their working men so that there could be further propaganda.

SIR FREDERICK MOTT, K. B. E., M. D., F. R. S., said it was true that the disabilities produced by syphilis were colossal, and from an economic point of view it would be of the greatest value to the government to do everything they could to support this propaganda both from a health point of view and from an economic point of view.

Mr. H. WANSEY BAYLY, M. C., said the progress during the seven months of the society's existence had been most encouraging. When he first conceived the idea of forming this society he gathered that the majority of the medical opinion would favor such a scheme, and after consultation with Lord Willoughby de Broke and Dr. Saleeby the first small meeting of the Venereal Prevention Committee took place on September 22nd; a month later this committee formed itself into the Society for the Prevention of Venereal Disease and a provisional constitution was accepted. On December 10th our president raised the question in the House of Lords of immediate selfdisinfection as a preventive of venereal disease and asked for papers relative to incidence of venereal disease in Portsmouth Military Area. The Ministry of Health replied in a White Paper in February in which inaccuracy in former statements was admitted. Our membership now ran into hundreds and our grand committee, which was limited to 100, was full. During the first seven months of the society's existence we held two public meetings in London. The editorials of *The Lancet*, *Public Health*, *Medical Press*, *Medical Officer*, *Medical Times* and *National Health*, made it evident that these journals recognized the supreme importance of immediate self-disinfection as a method of preventing venereal disease.

American medical papers were mostly sympathetic.

The NEW YORK MEDICAL JOURNAL, in reviewing his book on venereal disease, which expressed the views of the society, stated: "The chapter on prophylaxis is extremely sane and wholesome and in marked contrast with the sentimental exhortation of elderly men influenced by their moral views." The nonmedical press was still rather shy, with the exception of the *Times*, which had published three leading articles in support of our movement and four letters from the Executive Committee. Branches of trade unions were showing a keen desire to hear lectures on the subject of the prevention of venereal disease, and he was now giving two or three lectures a week to most appreciative and intelligent audiences.

To stamp out venereal disease was a noble goal, and if this goal were achieved it would be cheaply bought at the expenditure of all our lives and all our money. In this small society centred the principle that it was immoral to withhold a scientific truth from the people, the knowledge of which would diminish disease, pain and sorrow. We were but an obscure few, a voice in the darkness, but it was possible that we might achieve a niche in history as a society which dared range itself in opposition to clericalism and the government and which added to the sum of human happiness in spite of this opposition by appealing directly to the innate sanity of the people.

THE DIAGNOSIS OF INFLAMMATIONS OF THE MALE URETHRA.

By ABR. L. WOLBARST, M. D.,

Cystoscopist and Chief of the Urologic Clinic, Beth Israel Hospital; Consulting Urologist to the Central Islip and Manhattan State Hospitals.

At first glance it may seem almost superfluous to discuss the diagnosis of urethritis, the subject is apparently so simple and elementary. In fact, however, the subject is neither simple nor elementary, to which statement any patient who has been a victim of an erroneous diagnosis readily can testify from his bitter experience.

It is essential to remember primarily that urethral infections vary considerably as to their etiology and the clinical manifestations will reflect in great measure these variations in the causative factors. We recognize two kinds of urethritis: specific urethritis, in which the gonococcus is the predominating etiological factor, and nonspecific urethritis, which includes all the other kinds of urethral infections.

When a patient presents himself with a urethral discharge and other symptoms indicating an inflammation of the urethral canal, we are brought face to face with the task of determining the nature of the infection in order that appropriate treatment may be instituted; and the first step that must be taken is to determine whether we are dealing with a specific or a nonspecific infection, and if the latter, what is the underlying factor in the case.

Unfortunately, it is probably within the truth to say that this is not the usual procedure. The task of determining the precise nature of the urethral infection is not an easy one, and the busy practitioner does not readily find the time that must be devoted to it if it is to be attempted conscientiously. Usually the presence of a discharge, purulent urine, and urinary discomfort are considered sufficient to make the diagnosis of gonococcal infection, but the experienced practitioner sooner or later learns to his regret and mortification that this procedure is not always fair either to his patient or to his own reputation.

Let us first consider the nonspecific urethritides. Luys (1), referring to the organisms which have been found in nonspecific urethral discharges, mentions a formidable array, the following being among the most important: streptococcus, bacillus coli, pneumococcus, staphylococcus, various Sarcinae, diphtheria bacillus, tubercle bacillus, Micrococcus

fallax, and Micrococcus cereus albus. In addition, we may include perhaps the most important and the most frequently encountered—the Micrococcus catarrhalis. Then there are the so-called aseptic inflammations, in which neither the gonococcus nor other organisms can be found. The microscope shows nothing but pus cells, a few epithelial cells, and occasionally strings of mucus.

It is of supreme importance to know whether we are dealing with an undoubted gonococcus infection or one of the nonspecific types—not alone because our treatment must depend on this differentiation but because extremely vital social and economic questions may be involved. Still more important is the fact that these nonspecific inflammations do not respond kindly to the measures which are often inflicted on the patients in the belief that the gonococcus is the offending organism.

The expert urologist, accustomed to seeing patients who have refused to get well under the persistent administration of silver salts and astringents, will frequently score a decided hit if he will recognize the nonspecific character of the disease and adjust his therapeutic measures in accord with these findings.

THE TYPE OF INFECTION.

It is therefore evident that if our therapy is to succeed we first of all must know what sort of infection we are dealing with. Familiarity with the use of the microscope is a *sine qua non*, but that is not enough. One should be able to correlate the microscopic findings with a thorough knowledge of the clinical symptoms presented by the patient. In a great measure this knowledge can be obtained only through extensive clinical experience. This is true of all knowledge, but with this knowledge must come wisdom—the ability to differentiate the clinical manifestations of specific and nonspecific infections.

This is particularly true in the urethral inflammations produced by the Micrococcus catarrhalis. For all practical purposes there seems to be no difference between the symptoms of acute catarrhal inflammation and the typical gonococcus infection, yet there is a decided difference if one has acquired the ability to observe and detect it. The symptoms generally are less severe; the discharge is less profuse, it is likely to be more watery or mucoid in its character from its incipency; the urinary discomfort may be slight or absent; the

meatus is but slightly or not at all inflamed. As the case proceeds, we are impressed with this unusual mildness throughout its course, and if the urethral mucosa is not irritated by strong local applications recovery almost certainly follows without complications or other distressing symptoms. Associated with these phenomena there may exist a general condition of diminished vitality, evidences of a catarrhal diathesis in other parts of the body, and evidences or history of alcoholism or sexual excesses.

THE MICROCOCCUS CATARRHALIS

In dealing with the *Micrococcus catarrhalis* we are confronted by the extreme difficulty of distinguishing it from the gonococcus, since it bears so close a resemblance to the gonococcus in almost all respects that it can be differentiated only by culture. This organism grows profusely on agar, and in this respect it differs materially from the gonococcus and the meningococcus which it closely resembles in other characteristics. It does not necessarily follow, however, that a urethral inflammation is to be considered as an acute catarrhal condition because it happens to be mild in character. Every urethral discharge must be regarded with suspicion and considered potentially gonorrhoeal unless it is proved otherwise; but it is the part of wisdom to keep one's eyes alert to all the possibilities and to use every means at one's disposal whereby doubt and suspicion may be replaced by certainty and conviction. Whatever treatment is instituted should be administered with caution and the developments should be watched closely. If it is found that medication is increasing the inflammation instead of diminishing it, we must recognize that nature is presenting us with substantial evidence (if we could but understand her warnings) that our treatment is unsuitable to this particular case of specific infection or that the infection is not gonococcal at all. In either event it is well to have a culture made and determine definitely whether we are dealing with the gonococcus, the *Micrococcus catarrhalis*, or some other organism.

On the other hand, occasions may and often do arise which require an immediate answer to the question whether or not a certain urethral inflammation is actually gonococcal in character, without waiting for clinical corroboration. In such cases if the microscope cannot decide the question, we are of necessity reduced to the single expedient of making a culture of the urethral discharge, and abiding by its results.

THE COLON BACILLUS

The colon bacillus is not an infrequent factor in the production of urethral inflammation, especially in persons suffering from rectal and intestinal disturbances. Clinically the cases resemble the catarrhal infections. The microscope shows an utter absence of diplococci but a culture reveals the colon bacillus. In a case which I saw recently through the courtesy of Dr. Herman Roth of this city, the inflammation began as a distinctly Neisserian infection—typical both clinically and microscopically. Several months after all evidences of the inflammation had disappeared under appropriate treatment,

in the patient, while traveling, there suddenly developed a severe acute prostatitis followed by a urethral discharge which contained no organism but *Bacillus coli*. Under treatment, the prostatic inflammation diminished perceptibly and was succeeded shortly after by an orchiepididymitis with suppuration. At operation, the entire epididymitis was found to be involved and the testis proper presented a number of suppurating foci. Numerous microscopic examinations and cultures of the discharge and the urine have been made repeatedly, and nothing has ever been found but the *Bacillus coli*.

OTHER NONSPECIFIC TYPES

The remaining nonspecific types of urethritis are so rarely encountered that they need only be referred to, with the warning that they should be kept in mind in every case which departs in any appreciable degree from the classical specific urethritis. Principal among these are the pyogenic or purulent urethritis following the introduction of unclean catheters or sounds into the urethra. Instead of the gonococcus, pyogenic bacteria are found in the discharge. Not infrequently there may be an appreciable elevation of temperature, due to toxic absorption. The same conditions sometimes develop as the result of *coitus in oram*; in these cases, the normal flora of the mouth may be recovered in the urethral discharge.

The urethritis which accompanies the development of a syphilitic chancre at or within the urethral meatus is less frequent. This type is most deceiving, even to the conscientious and skillful observer, for the meatus looks red and swollen, the discharge is rather profuse, and the urine is purulent. Gonococci are absent. One's attention is attracted, however, to the character of the meatus. The lips are rather whitish and shiny; they stand apart instead of approximating, and when felt between the fingers the typical induration of the initial lesion can be perceived. It goes without saying that the intra-urethral chancre cannot be felt at the meatus, but it is not rare for the keen observer to locate a chancre in the urethra by the sense of touch. The induration at the site of the lesion is distinct and unmistakable.

Chancroidal infection of the urethral meatus resembles the type just mentioned except that there is the chancroidal wormeaten ulceration, without induration, at the site of the infection. A painful inguinal bubo tending to suppuration is a frequent early accompaniment, and immediately should attract particular attention to the unusual character of the urethritis.

If the lesion is phagedenic in character, destruction of the meatal lips and urethral walls proceeds ruthlessly and without abatement until the process is halted. Treatment seems to be of no avail. In a case under my care some years ago, fully an inch of the urethra was destroyed in this way in spite of (possibly because of) the most conscientious and vigorous efforts. The destruction ceased only after the patient had been saturated with mercury and iodide—a combination which has been found very useful in these cases. For several weeks this man had been treated for gonorrhoea by his attending physician before the chancroidal lesion was noted.

THE GONOCOCCAL TYPE.

Having considered the most important nonspecific types of urethritis, the acute specific gonococcal type presents itself for our attention. With the unusual types in mind, the diagnosis of acute gonorrheal urethritis is a fairly simple matter. I was taught many years ago by a former preceptor, Dr. M. W. Ware, to look for the typical acute gonococcal triad, angry meatus, profuse discharge and purulent urine. Experience has borne out the correctness of this teaching. When corroborated by the microscopic finding of the gonococcus, whether the gram stain or the simple methylene blue, or the Unna-Pappenheim differential stain, there can be very little possibility of error in the diagnosis. It is well to repeat this acute specific triad: angry meatus, profuse discharge, and purulent urine. If one or more of these symptoms is wanting, the case should be regarded with suspicion until all doubts have been removed, but the absolute diagnosis never should be made without the positive bacterial finding.

Frequently a recurrent chronic urethritis will present the discharge and the purulent urine; in such cases the angry meatus will be lacking, and the gonococcus may not be found in the secretion. It is rarely that a chronic urethritis will present the red, angry, and swollen meatus that characterizes the acute infection. When it is present, one may safely act on the theory that an acute process has been superimposed on a chronic infection, either from without or from within.

It is well to remember an important diagnostic feature in this connection. If the practitioner will take the trouble to examine a large number of urethral discharges microscopically and study them carefully, he will observe that leucocytes predominate in the acute infection with few or no epithelial cells; whereas in chronic infections epithelial cells appear in much greater number and the leucocytes are diminished in quantity. A knowledge of this fact will often assist materially in determining whether the infection is a new one or merely an acute exacerbation of an old inflammation.

In the diagnosis of urethritis this fact is important to know and remember, in so far as it helps to determine whether we are dealing with a new infection, or an exacerbation of an old one. It is of great importance to determine this distinction because the therapy of the two conditions is decidedly different.

The next step in order but not less important, is the determination of the extent of the inflammation, that is, whether it has been confined to the anterior urethra or has passed beyond the cut off muscle into the posterior urethra. Generally, when the patient voids urine into two cylinders, if the first is purulent and the second clear, it is safe to assume anterior involvement. Both glasses purulent, usually indicates anteroposterior involvement. To make certain, it is advisable to do the simple two glass irrigation test (Smith) from time to time during the course of the disease. This test, as well as others devised for the purpose of determining the source of the pus in the urine, has been fully described by me in previous publications (2).

Additional evidence of extension to the posterior

urethra is the development of urinary symptoms, frequency, dysuria, perineal discomfort, chordee, and a feeling of fullness in the rectum usually proportionate to the degree of swelling and inflammation of the prostate and seminal vesicles. The irrigation tests, however, will reveal the existence of posterior involvement long before the patient may present any symptoms pointing thereto.

When we approach the subject of chronic urethral infections, we are treading on treacherous and difficult ground. Here the problem is much more complicated and a correct solution can be arrived at only through most careful clinical observation and study.

CHRONIC URETHRITIS

The symptoms of chronic urethritis vary considerably. The most frequent symptom is a urethral discharge, usually designated as the morning drop; less frequently, there is an elusive discharge which haunts the patient at odd times; he cannot say what particular time of the day it is likely to appear. Both of these types may be most provokingly elusive in character. The patient may swear by all that he deems holy that he sees a definite drop every morning or every afternoon; he describes it as to quantity, consistency, and color; but when he is asked to come to the consulting room in the morning, retaining his urine all night, he is usually compelled to admit (much to his regret) that there is no discharge present and the urine is absolutely clear and sparkling. "But," he insists, "yesterday there was a discharge," and he is sure there will be a discharge "tomorrow." I have been unable to explain the elusiveness of this particular kind of morning drop except on the theory that it is produced only as the result of milking the urethra for a sufficiently long period to squeeze out all the accumulated urethral matter. It is a good policy, however, to minimize the importance of any discharge that has to be "milked" before the first morning urine is passed. The adoption of such a policy will do more to reassure and satisfy a worried neurasthenic patient than anything else known to me. One must be discreet, however, in the manner in which this favorite possession of the neurasthenic is eliminated from his accumulation of complaints.

In any given case involving a chronic urethral discharge, morning or otherwise, the first question to be decided is: Where does it originate? This cannot be determined by the urethroscope nor by the patient urinating in three, five, seven, or twenty glasses. A careful study and application of the tests above referred to must be made before any diagnosis or therapy can be determined upon. If, however, there is the slightest ground for suspicion that the pus in the urine is derived from the bladder or higher up in the urinary tract, the five glass catheter test (Wolbarst) will provide definite information that will eliminate any existing doubt (2).

Now, having determined the origin of the pus or shreds, the next step is to locate the lesion and determine its character. When the physician has solved these two problems correctly, his patient may consider himself a lucky man; he is half cured. Every case must be studied on its own merits.

The most frequent cause is stricture; less frequently, are folliculitis, prostatitis, vesiculitis, and all their respective variations. Occasionally a case will be encountered in which one cannot discover the existence of any of the conditions just mentioned; but a careful examination made with the posterior urethroscope will reveal a well defined inflammation of the verumontanum and the adjacent urethral roof, floor and walls. The moral to be learned from this observation is that no examination of a case of chronic urethritis is to be considered complete without a urethroscopic examination covering both portions of the urethra. If the physician is not in a position to make this examination understandingly, it is unfair for him to undertake the diagnosis and treatment of such a case. Stricture in the anterior urethra cannot be diagnosed by the passage of a sound, as is so frequently attempted. If the urinary meatus is a large one, the *bougies à boule* are satisfactory but time consuming and wearing on the patient's patience and good nature. The Otis urethrometer is a decidedly useful and practical instrument, and if it is in good working order may be considered reasonably exact in the information it conveys. Unfortunately, it cannot be employed in the posterior urethra, in which the steel sound and the urethroscope must be brought into requisition. If the urethrometer, dilated up to 29-30 F., passes through the anterior urethra without impinging on an obstruction, there is no appreciable stricture of any account in that canal. It is wise, however, to increase the dilatation as high as 33-35 F., because distinctly appreciable obstructions are sometimes encountered at that figure. These may consist of fine bands of tissue or swollen follicles projecting slightly into the lumen of the urethra. These fine projections may and often do produce the continuing discharge. The urethroscope must be brought into requisition for the exact determination of their number and character, and the treatment required to relieve the patient of them. The diagnosis of chronic urethral folliculitis is made by the urethroscope unless the infected follicles are situated so far forward as to be visible to the naked eye.

Prostatitis is found in practically every case of chronic urethritis, possibly because nearly every prostate examined is more or less congested, and it is not an easy matter to draw a sharp line between the normal congestion and the pathological inflammation. A prostate that is larger than the average normal organ, tender on pressure, and exuding abnormal material after massage, must be considered pathological. Considerable enlightenment as to the diagnosis is afforded by a study of the urine voided after a fairly vigorous massage of the prostate. It is well to have the patient retain his urine as long as possible, from six to ten hours preferably. He then voids half an ounce in one glass. This urine may be absolutely clear, or it may contain a small number of fine shreds. The prostate is massaged while the patient holds a clean glass slide under the urinary meatus. The massage is continued until some of the secretion has fallen upon the slide. The patient then voids all his urine, and this urine is studied carefully. If it is still clear or but slightly

hazy, the prostate may be considered normal; in a typical case of chronic prostatitis this urine voided after massage will be found purulent to a greater or less degree and may present large masses of broken down detritus which are nothing else than purulent casts of the prostatic follicles. The important thing to remember is that clear urine voided by the patient does not necessarily mean a normal genital tract. Prostatic inflammation first must be eliminated, and this can be done only by massage and study of the massaged secretion. It need not be emphasized that the massaged secretion should be examined microscopically at frequent intervals, with particular reference to the presence of gonococci and pyogenic bacteria. The disappearance of gonococci and the decrease and ultimate total absence of other organisms from this secretion is the most convincing evidence possible of the restoration of the prostate to the normal.

What has just been said in connection with prostatitis applies in all respects to the subject of chronic vesiculitis. In point of fact, these organs are so closely interwoven, both anatomically and pathologically, that it is well to consider them practically one. Some writers maintain that they can obtain the vesicular secretion without contamination with the secretion from the prostate; but the common experience of most clinicians is that such claims cannot be substantiated except in rare cases. The anatomical conformation and position of the vesicles is such that it is practically impossible for the index finger in the rectum to strip them of their retained secretion, as can be done with the prostate. There are exceptional cases, of course, in which they hang low and are very large, and thus can be manipulated, but these exceptions are rare indeed. However, if perchance the vesicular secretion can be obtained uncontaminated with that from the prostate, it is highly desirable to take advantage of the fortunate circumstance and the secretion thus obtained should be studied both macroscopically and microscopically.

A clear understanding of the points made in this discussion of the differential diagnosis of urethritis will often produce results that will be most astonishing and surprising to both the physician and his grateful patient.

SUMMARY.

1. A correct diagnosis in urethritis means half a cure.
2. In acute urethritis the etiological factors must be determined to a certainty before treatment can be begun. The principal factors to remember are the gonococcus, *Micrococcus catarrhalis*, and the *Bacillus coli*. Next in importance, the extent of the inflammation must be determined. Extension to deeper structures must be recognized immediately.
3. In chronic inflammation, stricture, folliculitis, prostatitis, vesiculitis, and colliculitis are predominating causative factors. The diagnosis must be arrived at through precise scientific measures, not through guesswork.

COMPARATIVE ANATOMY OF THE
GENITOURINARY ORGANS OF THE
LOWER ANIMALS.*

BY HENRY TUCKER, M. D.,
Philadelphia,

Curator, The Academy of Natural Sciences of Philadelphia, Fellow
of the College of Physicians, Member Philadelphia
Genitourinary Society, etc.

The character of this paper makes it necessary for me to review, in a superficial way, the embryology of the organs of generation, as in many of the lower vertebrates the adult condition is a counterpart of that found in some period of development of the human embryo. All of the genitourinary organs are intimately associated in their development. The essential kidney consists of a tube open at the distal end from which are given off diverticulæ terminating in blind sacs. Such a kidney is present in adult life in some of the lowest types of fishes and as a transitory condition in the human fetus.

In the human embryo the common duct running from end to end of the body on either side of the notochord is known as the Wolffian body. It is developed from the skin sensory layer and acts as the primitive kidney, to terminate in the cloaca. With the further development of the Wolffian body there is formed at the same time the so-called indifferent body to become the future ovary or testicle. Such a condition is of short duration, there being developed out of the posterior part of the Wolffian duct near its entrance into the cloaca a secondary duct, the primitive ureter; this gradually elongates giving off diverticulæ, as noted, which become the renal tubules and are disposed in reference to the blood vessels exactly as were the diverticulæ of the Wolffian body.

The urine excreted passes into the posterior part of the stalk of the allantois, which, dilating, is retained in the body as the primitive bladder, later to separate from the cloaca and that part of the allantois that comes away with the umbilical cord. Thus are the permanent kidneys developed and replace the primitive, formed out of the Wolffian body, the duct of which does not disappear but separates into two distinct tubes the outer one still known as the Wolffian the inner as the duct of Müller. For a while the Wolffian duct still carries urine secreted by its tubules, but as the function is taken up by the ureter and the true kidney it is gradually transformed. If the individual is to become a male the body changes into an epididymis and vas deferens and carries the spermatozoa formed in the former indifferent body which is now a testicle; the duct of Müller persisting as the sinus pocularis, the homologue of the vagina. If the individual is to become a female the indifferent body produces eggs and becomes an ovary, the Müllerian ducts fuse together from below upward and become the vagina, uterus and Fallopian tubes—the Wolffian ducts atrophy but persist as the parovarian, which in certain animals, such as the pig, is patulous and opens into the vagina.

Early in intrauterine life the conjoined Wolffian

and Müllerian ducts pass into the expanded stalk of the allantois, the latter emptying with the alimentary canal into the cloaca. As the fetus develops the rectum separates and if the fetus is a female the united Müllerian ducts have a distinct opening lying between the urethra and the rectum. The urethra, if the fetus is a female, passes beneath the clitoris or female penis—the two adjacent folds of skin become the labia minora, the external the labia majora, the ovaries remaining in the body cavity. If the fetus is to be a male the urethra passes through the penis, the underskin of which is formed by the coalescence in the midline of what in the female is the labia minora, the scrotum being formed by the fusion at the raphæ of the labia majora, the testicles descending through the inguinal canal to the scrotum pushing in front of them their peritoneal investment to form the tunica vaginalis testis.

Bearing these points in mind hermaphroditism is possible by a diverse development of the sexual units, i. e., the indifferent body, the Wolffian and Müllerian ducts, but is hardly possible in the higher animals, though it does obtain in some lower forms, as the mollusca, worms, and in many plants, the stamens and pistil of the flowers forming the male and female organs respectively. In all vertebrates the sexes are distinct and the individual is developed from an impregnated ovum of a similar specie.

Starting with the lowest type, the fishes, the primordial kidney (Wolffian body) is persistent and excretes the urine from the venous blood. I shall not dwell in detail on other anatomical peculiarities that separate the four great divisions of vertebrates—fish, reptiles, birds and mammals. Fish exist and breathe in water. Some retain the primitive vermiform shape and develop no limbs; in others the fins are simple, move on one joint and are only adapted for propulsion or guidance. The body surface is either smooth or covered by scales. The brain is small, consisting merely of a succession of ganglionic nerve masses connected with the organs of special sense. Touch is feebly developed. The tongue as an organ of taste is hardly apparent and functions chiefly in the act of swallowing or breathing. There is no external ear. The internal ear or labyrinth is present with largely developed semi-circular canals, the cochlea rarely has a separate chamber but is lodged in the cranial cavity with the brain. The eyes are large, not protected by eyelids and have no lacrymal apparatus. The alimentary tract is short and simple. The esophagus is hardly to be distinguished from the stomach. The heart consists of one auricle receiving the venous blood, and one ventricle, to propel the blood to the gills for aeration, by the minute bubbles of air suspended in the water, taken into the fishes' mouth; from the gills the blood is circulated through the entire body being largely aided by local muscular contraction. The blood rarely has a temperature above the surrounding water.

Many fish have a hydrostatic air bladder between the alimentary canal and the kidneys which may communicate by a duct with the gullet. In reptiles as this structure becomes more highly specialized with increased vascularity and pharyngeal relations,

*Read before the Philadelphia Genitourinary Society, May 24, 1920.

the form changes to the cellular structure of a lung. The limbs acquire the character of feet, first two mere many jointed filaments as in *Lepidosiren*, then two fingers with elbow and wrist joints, as in land animals (*amphiuma*), next three fingered as in *proteus*, or four fingered but reduced to a pectoral pair as in *Lepidosiren*. From these gill retaining forms up to and including the *crocodilia* all cold blooded vertebrates with lungs are called reptiles. The heart has two auricles, the ventricle is imperfectly divided, so the venous and arterial blood are more or less mixed. The lungs are baglike, either single or in a pair of unequal size, with cellulovascular walls and are contained in a common thoracoabdominal cavity.

In the bird there are certain modifications. The air bag becomes obliterated by the multiplication of the air cells, so forming a spongy lung. A four chambered heart prevents mixture of the arterial and venous blood, so furnishing pure arterial blood to the body; the temperature is maintained at from 90° to 105° F., irrespective of the surrounding conditions. The lungs are fixed and communicate by air cells extending into the abdomen or other parts of the body. They are oviparous, have feathers, and the fore limbs are modified as wings.

In mammals the lungs are suspended in the thoracic cavity, separated from the abdomen by the diaphragm. They are hairy, give birth to living young with exception of the monotremes. All suckle their young. Although for convenience we can divide all vertebrates into hot and cold blooded, based on the character of the cardiac and respiratory system, this but tends to mask their many affinities. For example, the hot blooded birds with their complex lungs and heart by their genetic and developmental characters and their anatomical structure are more closely allied to the Saurians than to the warm blooded mammals, while the modern *Batrachians* (*frogs*, etc.) differ from other cold blooded air breathers by their developmental and genetic characters and closely agree with the fishes. The extinct *Pterosauria*, a flying reptile, with wings and air sac, links the birds with this class of reptiles. Other extinct orders, as *Ganocephala* and *Labyrinthodontia* show the artificial nature of distinctions between fish and reptiles and the close transitions that connect all cold blooded vertebrates.

Vertebrates might be divided into oviparous, including fish, reptiles and birds, and viviparous, containing mammals; second, into anallantoic or branchiata or allantoic or abranchiata; into *Hæmatothermal*, having spongy lungs and a four chambered heart and hot blood and *Hæmatocryal*, having a simple heart, less perfect lungs and cold blood. The first two classifications will not hold, as some reptiles and fish are viviparous, and the lower types of mammals as the *platypus* and *echidna* lay eggs. In the group of *Marsupialia* the young are not nourished by placental attachment but early placed in a maternal marsupium or pouch and nourished by milk forced into their mouths by contraction of a muscle surrounding the efferent milk ducts. The third classification will not hold, for certainly warm blooded birds are more closely allied to reptiles than they are to placental warm blooded mammals. So all

divisions are artificial and not founded on fact either in their present form or the forms of their fossil ancestors.

Taking these orders up in sequence I shall try to explain some of the peculiarities of the renal organs and the organs of generation. In all vertebrates there is developed at an early period an excretory organ consisting of a tube extending from each side of the cloaca forward along the dorsal region close to the spine, where numerous small blind tubes enter at a right angle. The long tube is the excretory duct; the blind tube entering into the distal end of the duct is the *Wolfian body* or rudimentary kidney. This condition persists in the fishes and acts as a true kidney by excreting urine. In the bony fishes the kidneys are long and extend through the whole of the greater part of the dorsal region of the abdomen. The ureters may open directly by a short canal into the cloaca as in the lampreys or into a urinary bladder in the higher types, either as a conjoined tube or two distinct canals. In the sturgeon the ureters receive the *vas deferentia* or oviducts in their course toward the cloaca, where they unite as a short duct to form the common outlet for the urine as well as the generative products. In the sharks this single canal terminates in a common penis or clitoris at the back of the anus within the cloaca.

In reptiles the kidneys are always distinct, two in number and more compact in form, otherwise resembling the fishes. In the higher types the *malpighian bodies* are demonstrable. In snakes the kidneys take the elongated form of the reptile and are flattened, divided into numerous overlapping lobes to accommodate themselves to the flexuosities of the body in which they are located. In most species they are unsymmetrically situated. The kidneys in the *Lacertilia* are shorter and broader than in serpents—this condition is even more marked in the *chelonians* or turtles. In the crocodiles the ureters terminate in a low papilla in the urogenital compartment of the cloaca behind the genital orifices. The forepart of the cloaca is dilated and the rectum opens therein by a valvular protrusion. The adrenals may or may not be present in different species of reptiles. The kidneys in *Batrachians* resemble the higher types of fishes.

The organs of generation in fishes present a progressive gradation from an essential gland, whether ovary or testicle being determined only by a microscopic examination of its contents, to a concentrated form of testicle, through to the development of a true vas, a seminal vesicle, and an intermittent organ with finally added claspers for holding the female during coitus. The female organs correspond closely to the male in their gradation. In all fish where the vas is absent in the male the oviducts are absent in the female. The male organs in *Batrachians* are the testes with their ducts and appendages, the seminal reservoir, a common excretory canal, and a terminal papillæ, but no true penis.

In the lizards and snakes the ducts from the kidneys and testes are distinct to the cloaca and terminate on separate papillæ, the testicles small and compact, abdominally placed and covered fully by peritoneum, frequently brightly colored.

They are much more complex and convoluted than in the Batrachian. The tunica albuginea is dense and firmly attached to the secreting portion of the gland. As is to be expected the testicles of the snakes are more elongated than in the lizards. The vas deferens goes along the kidney in short undulations to the cloaca terminating in papillæ near the beginning of the seminal groove. The penis consists of two invertible sheaths with a highly vascular lining membrane, bifurcating at the blind end, to which are attached the muscles of inversion and retraction for keeping them hidden in the base of the tail. The mechanism of eversion and erection is by tumefaction of the vascular lining, plus contraction of the constrictor basis caudæ and sphincter cloacæ. The surface of the everted and erect organ in many species is covered with either large papillæ or even in some retroverted scales like horny processes. As corresponding depressions are found in the bifurcated vagina of the female, it is evidently a provision of nature to prevent slipping during intercourse.

Lizards, due to their short and outwardly extended legs, and snakes, in whom external legs are totally absent, are obliged to use absolute vertical progression, so it is necessary that for the testes to be abdominally placed and the intromittent organs capable of retraction and lodgement in the base of the tail, to prevent injury when not in use. In turtles the testicle is elongated, the vas is large and compacted by many convolutions. Each vas terminates with the ureter in common papillæ, the spermatic orifice being near the bladder. The penis is short and is indicated when not erect by the seminal groove. Only the glans and the pointed end of the fibrocartilaginous part above it project from the surface of the cloaca. This is enclosed in a reduplication of the cloacal membrane which acts as a pseudoprepuce. On erection this fold is obliterated by eversion. The penis in fresh water and land turtles is longer and larger than in marine species, on account, probably, of the more domeshaped carapace. The urethral groove extends along the mid-dorsum becoming more deeply situated as it approaches the glans. On erection the swelling of its borders converts the groove into a temporary canal; it then appears to end in an orifice. The penis is composed of two corpora cavernosa cohering in the middle line and attached to the ventral surface of the cloaca and two median tracts of highly vascular erectile tissue, forming the walls of the median groove. This is lined with a mucouslike membrane. They arise by an enlargement analogous to the bulb and are continued forward to the glans. On each side of the penis is a canal, the proximal end communicating with the peritoneal cavity, the distal end ending chiefly in a reticulate sinus. The penis has two retractors arising from the ischium and extending along the ventral surface to the glans. This muscle folds up the penis on retraction at the same time closing the rectal orifice and that of the allantoic bladder. Erection is followed by eversion of the cloaca effected by the cloacal sphincter. In the Crocodylia the testicles are longer, the penis is single with a dorsal groove and resembles the foregoing genera with the exception that the peritoneal

canals do not penetrate the cavernous structure but open outwardly on papillæ situated on each side of the base within the cloaca.

From the foregoing it can be seen that lizards are allied to snakes by their double extra cloacal penis; tortoises are allied to crocodiles by their single intracloacal organ. The structure of the organ confirms the two types. In the females of the Batrachia the cloaca presents the following outlets, in front, the opening of allantois bladder, next the rectum, then the outlets of the oviducts, and finally the ureters. In scaled reptiles there is a rudimentary clitoris or some trace of the intromittent organ of the other sex. In snakes the termination of the oviducts are in semilunar fissures within the cloaca.

The accessory parts of some of the female reptiles are remarkable. As the temporary skin pouches on the back of some of the frogs—i. e., pipa, in *Notatrema* and *Opisthodelphys* there is a single large sac with its entrance above the vent. When functionally active it covers the entire back; when not it shrinks so as to be hardly visible. In the pipe fish and sea horse the male develops a marsupium or pouch in which the eggs are placed, hatched, and the young carried until they are able to shift for themselves.

ACQUIRED SEXUAL CHARACTERS.

I shall mention only a few of the acquired sexual characters. The newts acquire a dorsal crest and a broader tail fin, with swelling of the cloacal labia in both sexes. The Japanese salamander develops a claw on each digit of the forelimbs, the male frog acquires a dark swelling of the thumb so as to better hold his slippery mate. A number of the fish have claspers near the anal orifice for the same reason. The larynx of the toads and frogs hypertrophy in the spring, all reptiles develop a brighter color, as do the birds in their nuptial plumage. The buttocks and genitalia of some of the doglike apes, especially the mandrill, are wonderfully and gorgeously colored. In lizards and snakes the anal scent glands and in the crocodiles the submaxillary glands are active and give out a strong musky odor. In the mammalian, hoofed animals, especially, the scent glands increase in size and activity during the rut.

In birds, the few peculiarities met with occur in the male sex. The organs exhibit the essential characters of the oviparous type. The testicles are situated high in the abdominal cavity and never descend into a scrotum. The penis is either double as in serpents, when it is extremely small, or it is single, but no matter to what extent it may be developed it is simply grooved along the dorsal surface for the passage of semen. As there is no true urethra, Cowper's glands and the prostate are absent. The testicles are two in number and vary greatly in size and color in different birds. They are white in the falcon and the dove, pale yellow in the horned owl and the gallinule, bright yellow in the magpie, ruff ibis and oyster catcher, black in the partridge, heron and some seagulls. They have a strong tunic and are suspended in a peritoneal fold. There is a marked periodical variation in size, due to the short period of sexual activity, but this limited period is compensated by the frequency and energy of the

sexual act. For example, in the sparrow in January they are the size of a pinhead, while in April at the height of the breeding season the glands are the size of a large marrowfat pea; the left is usually larger than the right. The only suggestion of an epididymis is the remnant of Wolffian body. This part is frequently a different color from the testicle proper. The vas passes down to the cloaca beside the ureter; it may be dilated at its lower end into a false seminal vesicle. It ends in birds with a double penis in small papillæ in the urogenital division of the ureter. The base of each papilla is surrounded by a plexus of veins and arteries which serve as an erectile organ during the orgasm, when the fossa is everted and brought in contact with the likewise congested everted fossa of the female. In many of the birds that copulate in water a long single penis is developed to permit of a more efficient coitus. I shall take the drake as my example. The penis is a highly vascular part of the lining membrane of the cloaca continued from the front part of that cavity; in the passive state it is coiled up like a screw by the elasticity of its associated ligament. The vascular membrane gives off many small pointed processes arranged in transverse rows on either side of the urethral groove; these incline backward near the point of the penis. The elastic ligament is surrounded by cavernous tissue and terminates in the blind end of the evertible sac. A groove commencing widely at the base follows the spiral turns of the sac to its termination. The spermatic ducts open upon papillæ at the base of the groove. Therefore, this form of penis has a muscle by which it can be everted, protruded and erected.

In the ostrich the penis is attached to the front wall of the cloaca, the body is bent in a recess out of which it can be drawn and returned by muscles. It consists of two firm fibrous bodies, the fissure between which is covered by the cavernous erectile tissue bounding the seminal groove. It has no evertible sac formation. There is a third elastic cord internal to the cavernous substance which produces the twisted form. The organs of most birds resemble the fishes and frogs, while those of ducks are like the hemipenis of serpents and lizards, and the ostrich that of the tortoise and crocodile. In the female bird in early life both ovaries are the same size, but only the left develops, the right remaining stationary or finally completely disappearing. In the embryo the basis of the ovary appears in the same relation to the primitive kidney as the testis in the male. The clitoris of the ostrich arises from the anterior margin of preputial cavity of the cloaca and is grooved like the penis of the male and has similar muscles. A smaller clitoris exists in those birds in which the male has a well developed penis. Most birds in adult age show external sexual characters. In the eagles and hawks the female is larger than the male. In the gallinæ and similar polygamous birds she is smaller. In most birds the males have the more brilliant plumage, while the hen has a more or less protective coloring. An exception is the phalarope, but in this instance the male does the incubating, the female on the completion of ovideposition deserting the nest. The

comb and wattles of the cock demonstrate sexual cutaneous appendages. In swifts, swallows, crows, doves, and a majority of the waders the sexes are alike.

MAMMALS.

In mammals the external manifestations of sex are extremely indefinite in the moles, shrews and rats, and often require careful dissection to be determined. The male monotrema has the heel spur, the female marsupial has the pouch and is of smaller size. The male narwhal has a tusk; the cachalot the large head. In seals the canines are usually larger. This holds good in most carnivora.

External genital characters are marked in most orders as well as in many grass eaters. The male has the larger horns, when these characteristics are present. The lion has the mane. The elephant has the large tusks. In quadrumana up to and including the gorilla the male is larger and has bigger canines. In the orang and chimpanzee, as well as in man, the male exceeds the female in size and has a more abundant hairy covering.

The testicles in mammals are more complex and compact, the peritoneum adds a serous layer to the proper sclerous covering of the glands. In the majority they are extraabdominal all or part of the time and are contained in a skin pouch or scrotum. The epididymis varies in size and position in many species. In all the semen is conducted in coitus by a penis traversed by a canal or urethra which may bifurcate in the lowest orders. Additional secretions are added by the vesicular, prostatic and Cowperian glands, when these exist.

In monotremata each testicle is situated below the kidney, to which it is suspended by a fold of peritoneum. The vas arises from the upper pole of the testicle and is so transversely folded as to appear to prolong the epididymis to the neck of the bladder. The duct dilates at its distal end and terminates in a papilla in the beginning of the urogenital canal. Its proximal urethral opening is not in contact with the vas in the quiescent state. It is divided by a median septum into two lateral parts enclosed in a dense fibrous sheath. The whole penis, when collapsed and retracted, is concealed in a large preputial fold. The terminal half forms the glans, which in the ornithorhynchus has a quadrilateral form, the upper and lower surface of which is traversed by a marked groove. The exterior surface is covered with numerous hard epidermal spines. Its extremity is bifurcated, each lobe terminating in three or four large but softer spines. A levator muscle runs along the upper surface of the penis. This muscle arises by two lateral slips from the protrusive sphincter. The retractor penis arises from the base of the coccyx and is inserted into the origin of the penis near the beginning of the urogenital canal. The urethra begins by a small orifice at its root communicating with the termination of the urogenital passage. So with the action of the retractor penis and the sphincter cloaca it can be brought in contact with the terminal papillæ of the sperm ducts. Such temporary continuation of the urethra and seminal passages takes place only during the vigorous muscular and vascular engorgement of the parts during coitus, the semen being

expelled from one to the other without escaping into the cloaca. Under ordinary circumstances the urine is transmitted along the urogenital passages, escaping into the cloacal vestibule, there blending with the feces, as in birds. The seminal urethra continues single to the middle of the glans where it divides into two canals. Each branch runs along the middle of the bifurcation of the glans to the base of the terminal papillæ, where it subdivides into smaller channels opening on their apices. If you would slit the canal along its under surface, thus converting it into a groove, the male organ would be like that of the tortoise; and although the mammalian type of penis is manifest by a complete urethra, it resembles the lizards by the bifurcation of the glans. That the penis is essentially a sexual and not a renal organ is demonstrated by this complete separation of the urorethral from the semi-nourethral passage in the monotremata. Cowper's glands are of large size and their physiological relation to a true urethra is demonstrated by their presence in these egg laying mammals, while they are absent in egg layers with merely a seminal groove. The prostate and vesicular glands are absent. The function of the spur is unknown, but it may be used as a clasper during the sexual act.

In the marsupials the testicles are contained in a pedunculated scrotum in advance of the preputial orifice, the epididymis is large and loosely attached to the testicle. The vas passes along the muscle sheath formed by the cremaster as far as the abdominal ring, there binding down and back to terminate at the commencement of the urethra. There are no vesicular glands. As a homotype of the female vagina the prostatic urethra is longer and wider in the marsupials than any other mammals. There are three pairs of Cowper's glands. The penis consists of a cavernous and spongy portion. The separate origin of each lateral half of the spongy body constitutes a double bulb with a corresponding double accelerator-urinæ muscle for compressing its particular bulb. The two processes soon unite to surround the urethra but again divide to form a double glans in the multiparous marsupials, in which most of the ova are impregnated in both ovaries, i. e., phalangers, opossums, etc. In the uniparous marsupials, as the kangaroo, the penis is single.

Between the two extremes are the dasyure, koala and wombat. In the koala the glans terminates in two lobes, the urethra being continued as a bifurcated groove along the mesial surface; in the wombat the urethra terminates in similar grooves but the glans is larger and partially divided into four lobes. In the phalangers the glans is bifurcated and the papillæ horny. In *Perameles lagotis* each bifurcated division is perforated by the urethra, while in the phalangers and opossums a simpler groove is present. The retractor penis arises in the kangaroos from the middle of the sacrum, divides into two muscles behind the rectum to be inserted with its fellow at the base of the glans. In the marsupials, like the opossum which, having a bifid glans, enjoy a double coitus, there is a levator penis. This muscle is absent in the uniparous kangaroo. Another powerful muscle of erection is the sphinc-

ter cloaca which surrounds the base of the organ and by contraction compresses the venous blood supply. In all marsupials the penis when not in use is bent upon itself, retracted and hidden just within the cloacal orifice, from which it emerges as in egg laying vertebrates when erect.

In rodentia, such as squirrels, beavers, rats and mice, the passive penis is retracted and bent, with the glans directed backward within a prepuce which opens into and forms part of a common passage in which the rectum terminates. The testicles undergo a periodical increase in size with change of position, passing from the abdomen into a scrotum and being again retracted after the rut. Cowper's gland, the vesicular glands and prostate are present in all excepting the hares. In the porcupine the levator is inserted into an ossicle in the glans. The penial bone is large in the capybara. In the agouti the testicles during the rut are perineal in position. In the *cavia* (guineapig) the os penis is a large flat curved bone situated above the urethra extending to the tip of the glans; below the termination of the urethra is a wide eversible pouch armed with two large horny styles. The surface of the glans is covered with horny scales. In marmots the preputial sac is more distinct from the rectal orifice than in other rodents.

In insectivoræ (males) the descent of the testicles is better marked than in the rat family. In bats the prepuce is long and the penis pendulous. The glans offers strange modifications in some species. The os penis is well developed in the fruit eating bats.

In the armadillo the testicles lie above the rim of the pelvis and do not descend at the time of the rut. A similar condition prevails in anteaters and sloths. In the armadillos the penis is proportionately large, a condition to be expected because of the mechanical obstruction of the body armor. In *Bradypodidæ* the testicles lie between the bladder and rectum; the penis is rudimentary without a corpus spongiosum, as in birds. In females the vagina is divided by a fibrous septum. In *Cetacea* (whales, dolphins, porpoises) the testicles are always abdominal, the vas is short and convoluted. The penis commences by two cavernous cruræ enclosed in strong erectors arising from the loosely suspended ossicle of the same side. These crura coalesce into a single cavernous body. The glans is long and tapering. The corpus spongiosum commences by a bulbous expansion but degenerates as it penetrates the corpora cavernosa. When not erect the penis is hidden in the long preputial cavity, the orifice of which is well in advance of the vent; vesicular glands are absent. The *Sirenia* (sea cows and dugongs) have vesicular glands. The glans consists of semilunar side lobes including a conical process, on the point of which the urethra opens.

The testicles of the elephant (*Proboscidea*) remain below and beyond the kidney. Vesicular glands and a true seminal vesicle are present. There are four prostates, two on each side of the urethra. The corpora cavernosa of the penis is divided by a thick fibrous partition beneath which lies the corpus spongiosum containing the urethra, besides the ordinary muscles there are a large pair of levators.

In *Perissodactyla* (rhinoceros, etc.) the testicles are inguinal. The prostate resembles that of the rat,

being composed of long, slender blind tubes with glandular walls. There is no os. Retractors are present, as are levators and two suspensory ligaments. The total length of the flaccid organ is three feet nine inches; the circumference of the prepuce is one foot five inches. The glans is a long, slender, compressed cone with a truncate apex, and in the undisturbed state, measures one foot in length. The apex of the glans resembles a mushroom on a thick peduncle projecting from an excavation at the end of the glans, with a thin wall, like a second prepuce. On either side of the base of the glans there is a longitudinal thick oblong ridge with a heavy rounded border. The base of the glans penis of the tapir has an upper lobe as well as one on each side, beyond which it is continued forward, contracting and terminating in a truncate surface. The testicles are inguinal, lying in a sessile scrotum.

In the horse the scrotum is suspended nine inches beneath the anus, whence it is prolonged forward, to terminate in the prepuce. The corpora cavernosa is formed by the confluence of the crura without a vertical septum, the glans has two lateral semilunar lobes and at the apex a central pyramidal process. In the castrated horse the retractors of the penis atrophy. In Artiodactyla the chief distinctive character is the enormous development of Cowper's glands. The testes are perineal. The scrotum projects but is not pendulous. The penis shows a sigmoid flexure. The glans is long and pointed. The preputial opening is near the umbilicus.

The ruminants have no vesicular glands; the testicles are carried in a pedunculated scrotum. The glans is long and pointed and in the camel the apex is continued beyond the urethral opening and bent back. Preputial follicles are usually abundant, most marked in the antelopes, reaching enormous size in the musk deer.

CARNIVORA.

The sexes are hardly distinguishable in the seals. The testicles are imbedded in fat between the pubis and the thighs, and the penis makes no outward projection. The preputial orifice is inconspicuous. The glans is pointed and supported by a small os. The os penis of the walrus is massive, about eighteen inches in length. The scrotum when developed in carnivora is hairy and less pendulous than in ruminants. The os penis in bears may be six inches long. The prostate is well developed in the raccoon and other members of the genus *Meles*.

Canis.—In dogs, wolves, foxes, the scrotum is more prominent than in the Mustellines and plantigrades. The prostate is protuberant. The spongy tissue of the urethra expands suddenly and considerably at the base of the glans, which presents an ossicle. The blood is returned from the penis by two dorsal veins. These are compressed by action of the levators arising from the first caudal vertebra, then passing one on each side of sphincter ani to converge to the dorsum of the penis, crossing the veins and terminating at the base of the bulbous portion of the glans. So long as the levators are stimulated to contract after coition the distended glans forms a mechanical impediment to withdrawing the penis from the vagina.

In the hyena the prostate is large, there is no os

penis, the prepuce is large, covers the organ fully and is much the same color, so differing from the dogs. In the cat the glans is covered with retroverted callous papillæ, less numerous in the lion and tiger. The prostate is small, Cowper's glands large. In the nonerect condition the penis is bent backward.

Quadrumana.—In the aye aye (*chiromys*) the testicles occupy a sessile scrotum, the penis projects and is covered by a thin hairless prepuce. In the lemurs the penis has an ossicle and hangs conspicuously as in *chiromys*. In the higher quadrumana and platyine apes the scrotum is more pendulous with a prominent penis. In the spider monkeys (*ateles*) the glans is largely expanded. In *Macacus* the vesicular gland is large and lobate, the prostate large, the os penis small. The testicles are larger than in man and project on either side of the base of the penis. In apes and monkeys the preputial fold is absent.

The chief modification of the mammalian kidney is its composition of a seeming multiplication of simple kidney, with or without a common cortical envelope and an absence of the mammillæ. This last condition is present in the ornithorhynchus, in which the uriniferous tubules terminate on the concave surface of a small and simple pelvis. The ureter takes its course to the contracted neck of the bladder but terminates in the male in the urogenital canal below the vas, in the female beyond the uterine orifice, which thus intervenes between the ureters and the orifice of the urinary bladder. In other respects, save the termination of the ureters in relation to the bladder, the urinary system of monotremes adheres to the mammalian type. This circumstance of deviation places them near the reptiles. The urine in these animals may dribble out with the feces or flow back into the bladder. In either case it is expelled through the cloaca and not through the urethra. The penis in the male is used only for the transmission of semen. In all other mammals the urethra transmits both urine and semen. In some shrews and moles and in the slow lemur the clitoris in the female is perforated by a canal which is here used exclusively for the urine, the vaginal orifice intervening between the anus and clitoris.

The scope of this review does not permit me to take up the question of deviation of the female organs of generation, or the secondary sexual characters found in animals.

In closing, we must remember that we, as the highest order of mammalia, are not in fact so far removed from the lower types and that at one time in the past our first ancestor, a reptile, prompted by a warmer blood and a more efficient circulation, dragged its sinuous length from the alluvial slime to seek surroundings more congenial. By this first effort, be it accidental or otherwise, the chain of advance was started, so during the millions of years that have since elapsed we have developed link by link till now the human race stands at the top.

No claim of originality is made in this communication. It is, as stated, simply a review. I have quoted freely from many authors, among them Sir Richard Owen's comprehensive works on *Comparative Anatomy*, Flower and Lydekker's *Mammalian Zoology*, Dr. H. C. Chapman and other writers.

MODERN TREATMENT OF SYPHILIS.

BY OSCAR L. LEVIN, M. D.,
New York,

Attending Physician, Department of Dermatology and Syphilology,
Beth Israel Hospital and Cornell University Medical College;
Chief of Clinic, Department of Dermatology and Syphilology,
Mount Sinai Hospital, O. P. D.

In this article I shall epitomize the rationale of my methods of procedure in the usual case of syphilis. No attempt is made to describe special plans of attack employed for those special types of cases, like congenital syphilis, nor, for those cases where specialized tissues, like the nervous system, are involved. Of course, it must be understood that all measures conducive to the promotion of good health should be employed and that much depends upon the cooperation of the patient.

Syphilis is an infectious constitutional disease caused by the *Spirochæta pallida*. From a local point of inoculation, where the chancre develops, the organisms migrate with the blood stream and the lymph current to all parts of the body, causing anatomical and physiological changes in the organs. Thus, after a primary incubation period, and a localized initial lesion with enlarged adjacent lymph nodes, the infection, at the end of a second incubation period, usually of four to six weeks, manifests itself as a generalized condition. The infection is slowly diluted and appears usually at the end of a year or more by localized evidence of the disease. The course of the disease is, therefore, conveniently described in three stages; the primary, the secondary and the tertiary. The pathological changes of syphilis in all its phases are essentially the same and are characterized by the presence of a granuloma which is made up of a perivascular infiltration of small round and plasma cells. The various lesions are merely expressions of different degrees of intensity in the reaction of the tissues to the excitant. The older lesions are affected by a more marked endarteritis and periarteritis and a greater substitution of the cellular tissue by fibrous tissue.

It is evident that the cure of the disease depends upon the destruction of the spirochetes and the restoration of the normal anatomy and physiology of the affected tissues. The destruction of the organisms is effected by the administration of specific spirocheticidal remedies and the employment of measures to stimulate the resisting forces of the body. By the internal administration of iodides the spirochetes are destroyed, the pathological tissues are removed and the normal structure regained. With the destruction of the spirochetes and the development of normal tissue the normal functions return, which at times are aided by methods of reeducation. Where special tissues have been destroyed and replaced by scar tissue there may be no return of function or only a partial return.

THE SPIROCHETICIDES.

Arsphenamine and its congeners, and mercury are spirocheticides. While less bactericidal than mercury arsphenamine is a more powerful spirocheticide, exerts a more rapid and destructive action on the organisms and is a tonic to the system. Mercury is only slightly spirocheticidal but possesses

the power to stimulate the body to resist the syphilitic invasion, and favors the absorption of newly formed connective tissue. Therefore, arsphenamine is indicated in all phases of the disease, especially for the destruction of the spirochetes while they are still localized in the chancre and after they have invaded the system prior to their entrenchment behind obliterated blood vessels and masses of fibrous tissue. The drug will not cure syphilis in a single dose, nor, with rare exceptions, in a single course of several doses, but it will eradicate the disease when given in a systematic, scientific manner for several years. The combined administration of both specifics, arsphenamine and mercury, gives the best results. They destroy the spirochetes and stimulate the production of antibodies.

REMOVAL OF PATHOLOGICAL TISSUE.

Arsphenamine and mercury, by destroying the spirochetes, remove the factors which incite the formation of the pathological tissue and thus favor involution. Mercury also shows a tendency to stimulate the absorption of the poorly formed connective tissue. Iodides, once considered specific in their action, are now known to be without effect upon the organisms, but they are of immense value in removing abnormal tissue and opening the way for arsphenamine and mercury. The removal of the pathological tissue is possibly favored by the inhibitory action of iodine on the antiferments and thus permitting the normal proteolytic ferments to digest the infiltrations. By producing prolonged vasodilatation the iodides improve the circulation through the tissues. It is also possible that the action of iodides upon the thyroid gland may aid by stimulating the antiseptic action of the secretion and by promoting absorption of infiltrations. It has been said that the main signs of hypothyroidism depend upon the development of infiltrations and it has been shown that stimulation of the thyroid or the administration of the gland extract will cause the disappearance of these infiltrations.

VARIOUS PHASES OF SYPHILIS.

For purpose of treatment it is advisable to consider the three stages of syphilis as follows:

Primary stage.—This includes the primary incubation period as well as the phase in which the chancre and the adjacent adenitis are present; the spirochetes are localized and there is a negative Wassermann reaction of the blood.

Secondary stage.—a. A preflorid phase in which there is evidence of primary lesions usually still present, there is no clinical evidence of general syphilis, but the blood shows a positive Wassermann reaction. b. In the florid phase there are clinical signs and symptoms of active secondary syphilis and there is a strong positive Wassermann reaction of the blood. c. A declining or latent secondary phase which shows fading or no clinical evidence of secondary syphilis. The blood shows a strong positive Wassermann reaction.

Tertiary stage.—a. In the latent tertiary phase there is no clinical evidence of syphilis but there are positive biological findings in the blood or spinal fluid, or a positive luetin reaction is found. b. This

is followed by an active tertiary phase in which there is evidence of tertiary syphilis of the skin or viscera with or without positive biological findings in the blood or spinal fluid and a positive or negative luetin test.

SPECIFIC TREATMENT.

In view of the fact that in primary syphilis the spirochetes are still localized and the prognosis for a cure is most promising during this phase of the disease, the attempt is made to destroy the organisms *in situ* by vigorous, intensive treatment. Wide divergence of opinion exists as to the best manner in which the abortive treatment should be applied. There are some who advocate the administration of several doses of arsphenamine daily, while others assert that weekly injections of several moderate doses of the drug are sufficient. I have tried a medium course and have employed the following method of abortive treatment with success.

It is urged that the initial lesion or its scar if indurated should be completely extirpated whenever the site allows of such an operative procedure. By excising the lesion it is not proposed to cure or abort syphilis but merely to remove a possible focus from which spirochetes may invade the blood and lymph channels. In those cases where it is not feasible to excise the chancre, local cleanliness and the continuous application of a thirty per cent. calomel ointment are prescribed.

Combined administration of arsphenamine and mercury consists in the administration of four intravenous injections of arsphenamine in doses of three tenths gram at intervals of three days followed by a course of six intravenous injections of arsphenamine in doses of four tenths gram at five day intervals. Two days after the fourth injection of arsphenamine an intramuscular injection of a grain of mercury salicylate is given.

The mercury is then administered in the same dose two days after each of the last six arsphenamine injections. It is then continued in doses of one to three grains at intervals of five days until a course of twelve has been completed. As the chancre shows endarteritis and new connective tissue potassium iodide is prescribed in daily doses of thirty grains after the completion of the course of arsphenamine.

The patient is now given a rest from treatment for a month after which the Wassermann reaction of the blood is determined. If the reaction proves positive the patient is advised to undergo the plan of treatment which will be described for the declining phase of the secondary stage. A negative Wassermann reaction is followed by a course of four weekly injections of arsphenamine in doses of four tenths gram and twelve weekly injections of mercury in doses of a grain. A final Wassermann reaction of the blood justifies a lumbar puncture for examination of the spinal fluid. If the spinal fluid does not show any biological evidence of syphilis the patient is told that he is apparently cured but advised to undergo a general physical examination every six months and an examination of the blood every two months for a year and then annually for the rest of his life.

During the preflorid phase of the disease there

are no clinical signs of general infection although the Wassermann reaction of the blood is positive. It seems possible that such a positive reaction may occur early in the disease on account of the reagent which escapes into the blood from the initial lesion. In view of this and also because there are few spirochetes in the blood and they are not firmly established in the tissues the abortive treatment should be attempted. As a precaution against violent focal or general reaction five minims of a one to one thousand solution of adrenalin is injected subcutaneously prior to the first four injections of arsphenamine. The development of a reaction should be followed by the plan of treatment employed for the florid phase; the absence of a reaction warrants the further application of the intensive treatment.

During the florid phase the spirochetes are widely disseminated they swarm in the blood, invade all the tissues and overwhelm the general system before the natural resisting forces of the body are fully mobilized. The blood shows a four plus Wassermann reaction and the various clinical signs and symptoms of active secondary syphilis are present.

As there is no hope of completely eradicating the spirochetes by a course of intensive treatment during this phase and because violent reactions may result, a more conservative plan of attack is strongly recommended. The employment of arsphenamine at this time results in the destruction of large numbers of the organisms, the consequent liberation of an enormous amount of endotoxins which may intensify the local and the general phenomena of the disease and overwhelm the patient. This phenomenon is known as the Herxheimer reaction. The production of such a reaction in the nervous system gives rise to symptoms of temporary embarrassment or permanent destruction of tissue, as in the case of the third, seventh and eighth cranial nerves which traverse compact bony apertures and canals. It is therefore desirable to employ a method of treatment which diminishes the tendency to these reactions, destroys a certain number of organisms and favors the development of the resistance of the body to the invasion.

The procedures followed in florid syphilis may be described in three steps.

1. A series of soluble mercury injections. Mercury is spirocheticidal in action but to a far less extent than arsphenamine. Its employment liberates a much smaller amount of endotoxins and the possibility of reactions is much diminished. The use of the drug also tends to favor the development of the natural resisting forces of the body. Soluble mercury should be injected for this purpose because it is painless, absorbed quickly and the desired effect obtained rapidly. A two per cent. solution of mercury cyanide is injected daily for six days; the first dose of eight minims being increased one minim with each injection.

2. Combined arsphenamine and insoluble mercury injections. At the termination of the series of soluble mercury injections the patient is given six weekly injections of arsphenamine in doses of three tenths to five tenths gram. Two days after each injection of arsphenamine a grain of mercury salicylate is injected intramuscularly.

3. A course of insoluble mercury injections. Twelve weekly injections in doses of one to three grains are then administered.

This is followed by a period of rest during which potassium iodide is given. The Wassermann reaction of the blood is now determined. A positive reaction should be followed by a repetition of the combined administration of arsphenamine and mercury salicylate. A negative reaction after the first or second course of treatment should be followed by courses of four weekly injections of arsphenamine in doses of four tenths gram and twelve weekly injections of mercury salicylate with rest periods of two months for at least three years. The Wassermann reaction of the blood is determined at the end of each rest period. Iodides should be taken on and off during the entire course of treatment.

If the patient comes under treatment six months to one year after the appearance of the chancre, or the declining phase, we find reminders of lesions characteristic of the secondary stage and a strong positive Wassermann reaction. On the other hand, there may be no evident signs but subjective symptoms of the general infection and a strong positive Wassermann reaction.

In such patients Nature has been given the opportunity to resist the invasion of the disease. The antibodies in the blood and tissues are mobilized in sufficient force to repel the onslaughts of the spirochetes and gradually dilute the infection. The plan of therapeutic attack employed in this phase is similar to that in the florid phase but the preliminary course of soluble mercury is omitted. This omission is warranted because there is little or no danger from a Jarisch-Herxheimer reaction.

In the latent tertiary phase many syphilitic patients show no visible signs or subjective symptoms of the disease, yet upon testing the blood for the Wassermann reaction, a weak and at times a strong positive result is obtained. This latent phase develops a year or more after the onset of the infection and is occasioned by the attenuation of the infection by insufficient therapy in the past or by nature.

In those instances the spirochetes are not present in the blood but are entrenched in various localities behind fibrous tissue and vessels with partially or completely obliterated lumina. After a preliminary course of eight weekly injections of arsphenamine in doses of four tenths gram there follows a course of twelve weekly injections of mercury salicylate and iodides by mouth. At the completion of this course a period of rest from treatment follows and the Wassermann reaction of the blood determined. Subsequent to this courses of four weekly arsphenamine injections in doses of four tenths gram and twelve weekly injections of mercury salicylate are given twice a year for three years.

Iodides are given while the patient is receiving mercury and during the rest periods. I prefer giving the saturated solution of potassium iodide in essence of pepsin. The mixture is employed by pouring the required amount into a glass of milk and the curds which form are ingested after meals.

Evidence of active tertiary syphilis may develop at any time. The gummatous tumor which is the

characteristic lesion of this phase is made up of a dense mass of connective tissue, plasma and round cells and blood vessels with marked endarteritis. I have pursued the following scheme in the treatment of syphilitic patients with signs of visceral or cutaneous gummata.

1. The administration of potassium iodide in daily doses of one to two drams.

2. Weekly injections of arsphenamine until the disappearance of the lesions.

3. An injection of mercury salicylate two days after each injection of the arsphenamine.

4. With the disappearance of symptoms referable to the lesions, or of the lesions themselves, mercury is continued in weekly injections for three months.

5. Subsequent treatment is similar to that suggested for latent syphilis. In the presence of tertiary syphilis of the viscera this plan is generally employed but precautions must be taken against increasing the damage to the organs.

I recommend the routine method of treatment outlined above in those cases which run the usual course. The local treatment of syphilis may be obtained from the various textbooks and monographs. Criteria for an apparent cure are: repeated negative Wassermann reactions of the blood and negative clinical findings for at least one year after stopping treatment, a normal spinal fluid and a negative luetin skin test. Even in the presence of all these the patient who has once had syphilis is told to receive annual physical examinations and occasional Wassermann tests of the blood.

161 EAST SEVENTY-NINTH STREET.

THE CONQUEST OF VENEREAL INFECTION.

BY ETTIE A. ROUT,
London,

New Zealand Government Authorized Reporter and Honorable
Secretary New Zealand Volunteer Sisters.

Some fifteen years' experience as an official reporter in Australia and New Zealand, and some five years' work at home and in Egypt, France, Belgium and England gave me a general knowledge of the nature and extent of the venereal disease problem. The set purpose to send home as many clean men as possible was kindled by the vivid realization of what it meant to the women at home that in a few months some ten thousand Anzacs had become infected with venereal disease in Egypt. Moral measures having proved insufficient, obviously they must be supplemented by medical effort. Would this succeed? Then I did not know. Now my general knowledge, combined with several years' experience with the practical application of prophylaxis—mainly among overseas Britishers and Americans—makes me feel that victory is now attainable by all who are willing to think clearly and act courageously. Our worst failures in the army were due to the fact that we were caught napping. Our successes, and they are completely convincing, were due to the fact that we combined means of lessening contacts with methods of eliminating dis-

ease. Not merely must we try to prevent sin, but we must try to prevent the poisoning of the sinner; for if not, we shall have blind babies, invalid wives, and ruined husbands; broken hearted, broken bodied mothers each adding one more fragment to the Nation's pile of damaged goods.

Early in the war because of an outbreak of venereal disease in Egypt, one of our brigadier-generals visited a number of young, educated men in one of the camps, and asked for their viewpoint. They said that many of the men were influenced by the moral appeals made to them, but that a proportion of the men had indulged in this way throughout their adult life, and intend to continue to do so irrespective of anything medical officers, chaplains, or generals might say to them. That is the fundamental position which every reformer must face. So long as a number of men determine to adopt this policy, and so long as there is a sufficient number of women prepared to cater to them, the problem of venereal disease will continue to be acute in every country.

How then was venereal disease conquered in the Army? First, Was it conquered? It certainly was. Wherever prophylaxis was properly applied, at least two thirds of the cases of venereal disease were eliminated. That is the official statement of the American Army, and it coincides with that of the Canadian and Australian armies, on broad lines. In particular cases enormously better results than this were attained. For example, in August-September, 1917, over five thousand British troops came to Paris on leave without prophylactic measures being provided, and 1,038 became infected, over twenty per cent. Leave was then closed down; three prophylactic stations were established, and prophylactic tubes were issued, with the result that although during the next six months some twenty-five thousand to thirty thousand troops came on leave to Paris, the amount of venereal infection among them was reduced to less than three per cent.

By a special additional effort in Paris, backed up officially and unofficially by the Australian Army authorities, I succeeded in making the Anzacs the cleanest troops that ever came on leave to Paris. In five months we had only twenty venereal infections recorded against us at the Medical Report Centre, whereas many hundreds of infections were recorded against other troops. It is noteworthy that in November-December, a period of five weeks, when our supplies of prophylactic outfits ran out, we had twenty-four infections to our discredit, four more than during the previous five months. The most striking return was one furnished for the twenty-two days ending October 17, 1918, because a special medical effort was made to protect the Anzac troops during September-October, the result being as follows: Venereal infections recorded at Medical Report Centre, Paris, for twenty-two days ending October 17, 1918, no New Zealanders, no Australians, thirty-three Canadians, and twenty-four English, and a further return for the six weeks ending October 31, 1918, gave us only three infections among the Anzac troops and forty-two among the English. As the New Zealanders and Australians were the only troops given an unlimited supply of

prophylactic outfits, the conclusion is obvious. I am sure that when men and women are properly instructed in the mode of preventing infection, and are supplied with the necessary medicaments, venereal disease can be practically extirpated except among the drunken, and experience shows quite clearly that the vast majority of those who risk infection are not in a state of alcoholism when they do so; on the contrary they are able to take care of their health if they know how and the means are available. Further, the providing of these means does not act as an incentive to immorality: rather it is a continual reminder of the dangers likely to be incurred by loose and irregular relationship—hence a deterrent rather than an incentive to immorality.

Similarly the establishment of prophylactic stations was never misunderstood by the soldiers as an encouragement of vice, rather they argued that the menace to their health and efficiency must be extraordinarily great, or the Government would not incur the expense and deep odium of setting them up. Some differences of opinion existed among medical officers as to whether the issue of disinfectants, in a portable form, was advisable or not. Experience proved that disease could certainly be reduced by this method, and the danger to morality was merely a surmise, neither provable nor disprovable. Certainly experience proved that large numbers of men and women were able and willing to take suitable precautions to insure hygienic safety, and those who take the responsibility of suppressing a knowledge of prophylaxis from them must also be held responsible for the resulting spread of disease among the innocent—born and unborn. The hardest fanatic shudders from such a responsibility, and in the end is driven to admit that the world will not be rendered less moral by the abolition of venereal disease—only cleaner and happier for all of us.

Thus one hails with relief the news that the Portsmouth area, which has long been notable for the extraordinarily efficient control of venereal infection, secured by Sir Archdall Reid, by means of a potassium permanganate lotion, has now decided on the advice of its medical officer of health to apply the same system to the male civilian community. The following figures are interesting in this connection:

In 1917 the Army venereal disease rate for the whole of the United Kingdom was thirty-eight to the one thousand, and for Portsmouth town ninety-two to the one thousand; in 1919 the United Kingdom rate had risen to sixty-four, whereas Portsmouth town had fallen to fifty-four and four tenths, and Portsmouth area (Dorsetshire and Hampshire) to forty-seven and seven tenths, the Portsmouth area rate in 1919 minus disease imported from overseas being only thirteen to the one thousand soldiers. In France the increase was even greater among British soldiers than in the United Kingdom. In 1917 the British Army rate was twenty-seven to the thousand for 1917; in 1919 it had risen to over eighty to the thousand, and in 1920 it is still higher; whereas among the American troops, I am authoritatively informed, there has been

a steady decline. This would appear to be partly due to the simple and serious instruction in prophylaxis given to all enlisted men, and partly to the more adequate and efficient establishment and maintenance of prophylactic stations, and the much greater prominence given in American areas to the notice boards. Prophylaxis had been adopted officially; then it had to be put into proper practice; and the Americans were able to build up their system more surely and quickly because of their careful study of the past mistakes of other armies. Hence one is not altogether surprised to learn that under the supervision of the commissioner of health, Dr. Edward Martin, sixteen prophylactic stations have been established in different cities and towns throughout the State of Pennsylvania; and that, as part of the campaign against venereal disease, suitable packets of disinfectants have been put on sale in the drug stores. This is an extraordinarily valuable effort not merely to the United States of America, but to all English-speaking nations, for the social and sexual habits of all these nations are much the same. The American solution of the question of the distribution of packets strikes one as eminently practical. Most Anglo-Saxon communities are sufficiently advanced to accept the prophylactic station as a necessary institution, but they feel really anxious and unhappy about accepting the responsibility of distributing disinfectants, or on the other hand of forbidding such distribution. If private enterprises put suitable disinfectants on sale, the general public would prefer to accept this as evidence of the demand. It seems a pity they should be necessary, of course, but while they are necessary, it is a question of individual responsibility. All this proves there has been something wrong with the sexual education of men and women, let us try and do better with the next generation.

"The crux of the position lies with the woman, as regards the man we know pretty well what to do and how to do it. But as regards the woman, we neither know what to do, nor how to do it." These words were said to me some three years ago by a thoughtful Scotch doctor, in urging the necessity for establishing toilet rooms for women, a scheme he thought within the bounds of possibility, and more in accordance with Anglo-Saxon sentiment than licensed houses. One or two tentative experiments were made on the continent during the war, and we found that French and Belgian public women were quite ready to attend a Red Cross dispensary for prophylactic treatment, and quite ready to accept prophylactic outfits from the soldiers (we had the directions for women printed in French and English). In the licensed houses, of course, the women and the men always practised prophylaxis, and from properly conducted houses, such as those in Paris, we got practically no disease at all. But the mere existence of licensed houses in any area certainly offers no solution of the problem of venereal control, though personally I believe it helps to limit both disease and immorality to the classes of women to which it naturally belongs: that is, to the women who either cannot or will not refrain from the anti-social act of offering promiscuous and loveless relationship to men. Probably the majority of such

women are not bad at all but merely temporarily oversexed and perhaps going through a phase in the life history of the race which other women are born fortunate enough to avoid—and certainly most of the so-called bad women are willing for their own sake to take precautions against disease. Why then debar them from obtaining that knowledge in a clean and efficient manner? Doesn't one diseased woman spread disease much more than one diseased man? Why then confine ourselves to protecting men only?

As a fact, the advice we give to men is often quite useless, because it is given too late. If the man is already infected, and knows it, he will not trouble to apply prophylaxis. In a mercenary relationship, both parties are quite conscienceless. In marriage we have many cases of wives being infected by their husbands, and reinfected, and they will not let the doctors deal effectively with their husbands. The production of a health certificate by the man and the woman before marriage would lessen the number of such cases; but the spread of a knowledge of sexual hygiene among women would do far more.

Opposition to the spread of such knowledge can be removed by insisting on the fact that the venereal diseases are not immorality diseases. By typewritten circular letters and short lectures I have found no difficulty in putting this view clearly before thousands of soldiers during the war, and the inducements of self interest and reputation are enormously stronger among civilians than among soldiers; hence similar advice given quietly and straightforwardly to adult men and women would be even more effective in civilian life. Briefly, this is the advice I gave:

The microbes of venereal disease grow almost exclusively in the genital passages of men and women. If these passages are kept clean and disinfected, the microbes will not grow. Venereal disease does not always spring from immorality, or even from sex relationship, but from contact with infective matter. You had far better not risk such contact, but if you do, cleanse and disinfect yourself at once. Using some sort of grease beforehand prevents direct contact, the microbes will not pass through a film of oil, for they are gummy. They will not adhere to a greasy surface, hence they are easily washed off with soap and water after contact, and soap is destructive of the microbes—both of syphilis and gonorrhoea. It is seldom that a person who has used vaseline beforehand and soap and water afterwards becomes infected; if so, that merely proves that the precautions were carelessly carried out. Urinating immediately after contact is also a protection. Bathing with cold water is also protective. There is no excuse for doing nothing, and little excuse for delay; but if there has been delay, you should seek skilled treatment as soon as possible. The kind of precautions necessary to ensure protection is dependent on the kind of risk run. Only the persons themselves know the nature of the contact, the length of time occupied, the number of repetitions, and so forth. Contact with infective matter for a few moments is one thing; contact with infective matter for a whole night, quite an-

other. But every irregular contact is a risk; avoid risks, or if you disregard this advice, disinfect immediately. Do not let anybody persuade you that promiscuous relationship is safe. It never is, and do not let anybody mislead you into believing that disinfectants do not disinfect; they certainly do. If you become infected, the fault is really your own. You should not have risked infection; or, risking infection, you should have taken proper precautions. If you insist on making these your habits, then you had far better carry a town dressing with you, in the same way as a soldier carries a field dressing. You will give yourself a double chance of safety by taking your own emergency precautions, and reporting for prophylaxis at the prophylactic station as well.

From the Australian depots, prophylactic outfits were available without cost and small syringes and rubber protectors were on sale at nominal prices. In Paris we had twelve prophylactic stations, one English, two Canadian, one Australian, and eight American. We prevented as much disease as possible; when we failed, we cured as early as possible; and we did our best to reduce concealment to a minimum. Nevertheless, as a result of war and after war conditions, venereal disease has greatly increased in all the Allied and enemy countries; probably no European country has less than three or four times the amount of disease it had in 1913-14. Once in the life time of every generation, all mankind must pass through the bodies of its women. Shall we make and keep those bodies clean? Knowledge has given us power, and with this new power we shall be able to rid our nation of the most dreadful of all human scourges. Victory is within sight. When it comes sex will regain its loveliness.

RESULTS IN THE TREATMENT OF NEUROSYPHILIS

By PHILIP GOLDFADER, M. D.,
Brooklyn, N. Y.

Associate in Urology and Venereal Diseases, St. Mark's Hospital,
New York, and Clinical Assistant in Urology and Venereal
Diseases, Brooklyn Hospital.

A review of the results of treatment of neurosyphilis, as conducted by the urological service of the Brooklyn Hospital during the calendar years of 1918 and 1919, has proved of great interest to me and a brief survey of that review is presented here, with the hope that it may be of interest to those who are sceptical as to the value of intraspinal therapy. It is not my intention to disclose any new or startling discoveries in the treatment of neurosyphilis, but to state the results of treatment by a method which in our hands has given better results than the older methods.

In order to treat neurosyphilis, with a hope of obtaining results, treatment must be instituted as early as possible. Since the spinal fluid is involved in from sixty to seventy-five per cent. of cases during the secondary stage and in twelve to twenty-five per cent. of the cases the pathological changes of the fluid persists, it behooves us to be on the watch for early involvement of the central nervous system. A

lumbar puncture is therefore indicated in the following cases:

1. All cases coming under observation after the primary stage has passed, as a diagnostic procedure. This includes patients who have been treated and latent or tertiary cases where treatment has been neglected.
2. Patients who have been under active treatment for eight to twelve months, with no improvement in the blood Wassermann.
3. To differentiate between involvement of the nervous system of syphilitic and nonsyphilitic origin.
4. As a diagnostic measure before discharging a patient as cured.

During the two years covered by this report we performed diagnostic punctures in sixty-one cases, which included syphilitic patients who had symptoms referable to the nervous system and those who were ready to be discharged. Out of that number eleven, or eighteen per cent., gave positive fluid findings showing involvement of the central nervous system. Out of the eleven cases, two or three per cent., were in women. The smaller proportion of positive findings in women is due to the fact that we find it more difficult to convince women of the advisability of having a lumbar puncture performed.

During the same period we gave 210 intraspinal treatments to forty-two patients. The number of treatments given to any patient varied between one and thirty. The ages of the patients varied between twenty-one and fifty-eight. Between the ages of twenty and thirty, four patients, or ten per cent.; between the ages of thirty and forty, nine patients, or twenty-two per cent.; between the ages of forty and fifty, twenty-two patients, or fifty-two per cent.; between the ages of fifty and sixty, seven patients, or sixteen per cent. Of the forty-two patients ten were single and thirty-two were married, which also includes one single and one married female patient. Our series of forty-two cases were divided clinically as follows: Twenty-nine cases of tabes, or sixty-eight per cent.; twelve cases of cerebrospinal syphilis, or twenty-nine per cent.; one case of paresis, or three per cent. Our diagnosis in each case was determined by history, physical examination, blood Wassermann and spinal fluid examination.

The opinion held today by such syphilographers as Fournier, Kaposi and Newman, and by such neurologists as Heubner, Gilbert and Kuh, is that in those individuals who have had no antispecific treatment or insufficient treatment, syphilitic involvement of the nervous system is likely to develop. On the other hand, Collins in a study of ninety-six cases of tabes concludes that a thorough treatment of syphilis neither prevents nor postpones the development of syphilitic nervous disease which occurs later rather than earlier in cases not thoroughly treated.

In going over the histories of our series of cases, I was able to find references to early treatment in thirty-four cases only. In nineteen cases, or fifty-five per cent., the patients had had no treatment at all; in four cases, or eleven per cent., they had had only local treatment; in four cases, or eleven per cent., they had had mercury pills by mouth for vary-

ing periods; in six cases, or seventeen per cent., they had had one course of treatment, and in two cases, or six per cent., they had had two courses of treatment. In other words, in sixty-six per cent. of the cases the patients had had no constitutional treatment whatsoever before the onset of symptoms.

We have had a few patients in whom neurosyphilis developed a few months after the appearance of the initial lesion, even though they were energetically treated from the outset. There are no doubt several strains of *Spirochæta pallida*, some more potent than the others and some that have a predilection for nerve tissue. In a patient with lowered resistance and infected with a strain of a malignant type of spirochete involvement of the nervous system is more likely to occur with astounding rapidity in spite of early and well directed treatment. In the face of our results, we are convinced that the cases treated vigorously from the start are less likely to be complicated by neurosyphilis. Even though authorities disagree on the value of antispecific treatment in preventing involvement of the nervous system, we should not conclude from these observations that syphilis in whatever stage it is seen should not be thoroughly and energetically treated.

In our series the earliest involvement appeared seven months after the initial lesion in the form of optic atrophy. Our records also show some cases in which manifestations of involvement of the nervous system did not appear for thirty-eight years after the appearance of the chancre. The average duration of time for the appearance of symptoms referable to the nervous system was twelve years and eleven months.

The treatment employed in our series was the Swift-Ellis method, which in detail is as follows:

One hour after the intravenous administration of salvarsan (.4 to .6 gm.) forty mils of blood is withdrawn and allowed to clot, after which it may be centrifugalized. The following day twelve mils of the serum is pipetted off and diluted with eighteen mils of sterile normal saline solution, making a forty per cent. solution. The serum is heated at 56° C. for half an hour, after which it is ready for intraspinal injection. A lumbar puncture is then performed in the usual manner and the salvarsanized serum is allowed to run slowly into the spinal canal by gravity. The intraspinal treatments were given at intervals of one to three weeks depending upon the condition of the patient and the reaction following the injection. Treatments were given in courses of six to eight injections and intervals of four to six weeks allowed between courses.

Fordyce sums up the rationale of intraspinal therapy in these words: "It does not require the experience of a trained neurologist to convince these patients that their condition has been changed from hopeless invalidism to comparatively good health. The advocates of intraspinal therapy have never claimed for the method that it should be used to the exclusion of the intravenous, nor have they claimed that the choroid plexus is impermeable in all cases and that remedies introduced intravenously could not reach the cerebral or spinal tissue." The intravenous

administration of salvarsan can be employed in early cases of cerebrospinal syphilis (meningitis, meningomyelitis, meningoencephalitis), early cases of tabes, and syphilitic epilepsy. In these classes of cases, the improvement both clinically and serologically is fairly rapid under intensive treatment, but at times we see patients, who have not responded to intensive intravenous treatment, show marked and rapid improvement by combined intravenous and intraspinal treatments.

The following histories and laboratory findings are submitted as illustrations of our results with the Swift-Ellis method:

CASE I.—Diagnosis, tabes. F. H., a man, fifty-eight years old, reporting for treatment in November, 1917, with a history of chancre twenty years previously. Had had local treatment and the sore disappeared in a short time. For the last ten years had had shooting pains in lower extremities and occasional pains in joints. Walked with difficulty. Had incontinence of urine for several years which necessitated the wearing of a urinal. Physical examination revealed the following condition: An anemic male of slight build; fundi, negative; pupils, unequal and irregular, both light stiff; knee jerks absent; Romberg, plus two; sphincters, vesical incontinence complete; rectal incontinence at times; gait ataxic, facial and lingual tremors absent; toe-heel impossible without support; speech, slight defect on test phrases; mental condition negative; sensory, lancinating pains in legs; blood and spinal Wassermanns, four plus.

On November 15, 1917, the patient had albumin in urine; administration of salvarsan postponed. He received three injections of mercury salicylate at weekly intervals and increasing doses of potassium iodide. On December 6, 1917, there was no albumin in the urine, and he was given six Swift-Ellis treatments at weekly intervals. On January 17, 1918, the patient could hold his urine for three hours and the urinal was discarded. His gait was improved. For the next year he received weekly injections of mercury salicylate and moderate doses of potassium iodide.

In this case both clinical and serological improvement was satisfactory. The patient works all night and is able to hold his urine without any difficulty.

				4-15-20	negative

CASE II.—Diagnosis, tabes. S. Z., a man of thirty-three, reported for treatment in April, 1918, with a history of chancre nineteen years ago, followed by a maculopapular rash and sore throat. Did not receive any treatment until four years ago when he began to complain of a sore throat and stomach trouble. Was treated by his family doctor and at several hospital clinics where he received twelve salvarsan and about two hundred mercurial injections. At present complains of shooting pains in legs and back, dyspepsia, slight congestion of throat, spots appearing before right eye and difficulty in seeing with right eye.

Physical examination revealed the following: A

thin male with bony frame, fair musculature; fundi clear; pupils moderately dilated and fixed to light; Romberg absent; knees, right plus two, left plus minus; sphincters, O. K.; gait normal; Babinski absent; no facial or lingual tremors; no ataxia of upper or lower extremities; speech O. K.; mental negative; blood and spinal Wassermanns four plus.

Beginning April 4, 1918, he received six Swift-Ellis treatments at weekly intervals, followed by twelve mercury injections at intervals of four days with increasing doses of potassium iodide. Beginning July 11, 1918, he received six more Swift-Ellis treatments at weekly intervals, followed by weekly injections of mercury salicylate. The patient now feels much better and the pains in legs and back have disappeared.

7-19-18	10	negative	negative		
8-2-18	18	negative	negative		
9-20-19	10	negative	negative		

CASE III.—Diagnosis, tabes. J. W., a man of thirty-seven, reported for treatment in September, 1916, with a history of chancre fourteen years ago. Had trouble in walking for past two years, and for past four months had had lancinating pains in legs. He also suffered from headaches.

Physical examination revealed a thin male weighing 125 pounds. Pupils unequal and irregular, both light stiff; knee jerks absent; gait ataxic; speech, slight defect on test phrases; mental, memory for business affairs O. K.; distinct memory defects for articles used and acts performed in daily life; sensory, lancinating pains in legs; blood and spinal Wassermanns, four plus.

Between September, 1916, and July, 1920, he received ten intraspinal treatments, twenty-one treatments with salvarsan, about one hundred injections of mercury and potassium iodide administered internally. About March, 1917, he complained of severe headaches and tremors, the latter occurring when he was in bed, from no apparent cause, and referred especially to the left foot. After a few injections of mercury and potassium iodide internally, the headaches were relieved.

About October, 1918, our notes showed that he did not walk as well as formerly, his steps were heavier than usual and when he bent over he trembled. He was then energetically treated with ten intravenous injections of salvarsan when he improved somewhat. In February, 1920, he began to have difficulty in walking, with renewal of headaches. He was given four Swift-Ellis treatments and improved somewhat.

SPINAL FLUID		BLOOD WASSERMANN	
Date	Wass.	Date	Result
9-7-16	4 plus	9-7-16	4 plus
1-25-18	1 plus	3-16-17	negative
2-3-18	1 plus	3-6-19	negative
3-15-18	negative	7-2-20	negative
3-22-18	negative		
4-5-18	negative		
4-12-18	negative		
7-2-20	negative		

The records for the reports of the spinal fluid in this case were lost up to the spinal fluid taken

on January 25, 1918. The patient had received up to that time four intraspinal treatments, eight salvarsan treatments and thirty injections of mercury. In this case there was marked serological improvement, with but slight improvement in the symptoms.

CASE IV.—Patient I. P. Diagnosis, cerebral type central paralysis, involving right arm, right side of face, and right leg; date of infection September, 1917. Onset of symptoms, November, 1918. The patient had received six doses of salvarsan and twenty injections of mercury salicylate between infection and paralysis. Symptoms developed three months after cessation of treatment. He received three intraspinal treatments of salvarsanized serum and three treatments of mercurialized serum. In the course of treatment, edema of lower extremities and marked albuminuria developed which could not be accounted for by cardiac or renal deficiency under careful medical study. This edema was always less following lumbar puncture. The paralysis had completely disappeared, and on account of the edema and albuminuria we discontinued the Swift-Ellis treatments.

SPINAL FLUID		BLOOD WASSERMANN	
Date	Wass.	Date	Result
11-15-18	4 plus	11-15-18	4 plus
11-22-18	4 plus	7-7-20	negative
12-3-18	4 plus		
12-6-18	4 plus		
12-11-18	4 plus		
12-18-18	4 plus		
7-7-20	3 plus		

The patient could not take further spinal treatment at this time, but seemed to be in excellent condition. Even though there was improvement in the blood Wassermann and but slight improvement in spinal fluid, clinically he made an excellent recovery.

CASE V.—Patient, C. R. Diagnosis, tabes with optic atrophy. Date of infection unknown. The patient had had two courses of treatment, but had been two years without treatment. Had had four salvarsanized intraspinal treatments and three mercurialized serum treatments at weekly intervals. At time of beginning treatment the blood Wassermann was three plus; spinal Wassermann ten plus. At completion of this course of treatment, patient felt well, resumed work, and was absolutely steady on his feet, though totally blind.

SPINAL FLUID		BLOOD WASSERMANN	
Date	Wass.	Date	Result
6-10-18	10 plus	6-10-18	3 plus
2-8-19	5 plus	2-14-19	negative
2-14-19	5 plus		
7-8-19	5 plus		

This patient was improved clinically, with no improvement in his sight. He was seen too late for treatment to be of any benefit to his eye condition. Serologically he improved to some extent. We used mercurialized serum in this case because the patient had marked reaction after salvarsan.

With two exceptions, we have had no disagreeable complications in the treatment. In one case, the patient became delirious a few hours after the treatment and there was a transient paralysis of both lower extremities which cleared up entirely in one week. In another case of tic douloureux with symptoms for only six months jaundice developed after three treatments. With jaundice still present

he received another intraspinal treatment and died three days later, probably due to the overwhelming toxemia.

While we had a few cases in which we could see no improvement either clinically or serologically, we have had a few cases with brilliant results and definite results in a considerable number. We therefore feel that our results are better with the combined method of treatment, than we have been able to obtain with the intravenous method alone. Tabulated our results are as follows: Improved, twenty-seven, or sixty-four per cent.; unimproved, fourteen, or thirty-three per cent.; died, one, or three per cent.

I believe when properly performed intraspinal treatment is indicated as a routine in all cases of syphilis where clinical symptoms and examination of the spinal fluid indicate involvement of the central nervous system.

In conclusion, I wish to express my thanks to Dr. Nathaniel P. Rathbun and Dr. William F. McKenna for having permitted me to use the results of their private cases in compiling this report.

123 REID AVE.

SYPHILIS AS A CAUSE OF DELAYED HEALING IN THE NONINFECTED ABDOMINAL INCISION.*

BY WILLIAM EDGAR DARNALL, A. M., M. D.,
F. A. C. S.,

Atlantic City, N. J.

In 1914, Miles F. Porter discussed the question of delayed healing in the noninfected incision. He, however, confined his discussion exclusively to the epigastric region and sought to show the cause as due to the increased tension of the upper abdomen, or to the scantiness of the circulation in these tissues, or to nutritional disturbances of the nerve supply. There seems to be little or no literature on this subject, although nearly every surgeon of considerable experience has had one or more cases. Morris's article (1) is about the only reference to the subject. Morris thinks that the occurrence of delayed healing in the upper abdomen is due to trophic or neurovascular disturbance in the zone of Head.

Porter collected personal expressions from a number of surgeons. Some of these attributed the separation of the tissues to soiling of the incision with the contents of the upper bowel or stomach, inasmuch as most of the operations in the upper abdomen are performed on these organs. Others thought blood dyscrasia, malnutrition, and toxic conditions, such as advanced carcinoma, might be the cause; but Gerster significantly remarks that "back of all these there must lie biochemical causes as yet unknown to science." Madelung asks why the discussion of delayed healing should be confined to the upper abdomen, when eighty-two out of one hundred and fifty-six cases occurred in incisions below the umbilicus. Deaver sees no reason why

wounds anywhere in the abdomen should not heal, in the absence of infection.

None of these reasons seems to me to answer the question adequately. If it is due in the last analysis, as Bloodgood thinks, to catgut, why does not the same catgut used by the same surgeon in the same way not more often result in failure? As a matter of fact, these cases occur so infrequently that this can hardly be the reason. The same question may be asked if it is due to faulty technic or to infection, and yet busy surgeons of wide experience in each instance seem to be able to recall only a few cases.

Some have thought that the lack of union is most marked in, or wholly confined to, the deeper structures. The question may well be put: Why should a surgeon who has been constantly operating over a period of fifteen or twenty years in hundreds of cases, with a well developed and highly refined technic and employing methods of suturing which succeed and are expected to succeed in perfect incisions in practically all clean cases, suddenly be confronted with an incision which, when the sutures are removed at the usual time, opens to the bottom with no attempt at union of anything, not even the peritoneum, which ought to be sealed together in twenty-four hours, and with no evidence whatever of any infection? Why should it occur so rarely, if it is due to faulty technic, or catgut, or neurovascular disturbance, or lack of blood supply, or tension? Certainly these conditions occur so constantly that, if delayed healing is due to them, it ought to be as commonplace as the usual occurrences in abdominal incisions, such as stitch abscess, incisional hernia, and other conditions.

In my own experience, which covers an active service of nearly twenty years, I can find but three cases among hundreds of abdominal incisions. This comparative infrequency accords with the experience of most of those discussing the question, and also of those quoted by Porter. No surgeon seems to have had many cases, and yet almost all can point to a few. But if the few cases occurring in the practice of each of us could be collected and studied, the number in the aggregate would be sufficient from which to draw valuable conclusions.

Two of my cases occurred in patients with incisions below the umbilicus and one above. The first, a ward case, was that of a negress on whom I did a subtotal hysterectomy for large fibroids. The case was a perfectly clean one. There was no indication after the operation of any infection of the incision, either locally or constitutionally. We thought she was making a satisfactory recovery until the removal on the tenth day of the silkworm sutures from the skin. Then the whole wound fell wide open, peritoneum and all, so that one could look with unobstructed view to the bottom of Douglas's cul-de-sac. She became infected and died. This case occurred before the discovery of the Wassermann reaction, but the almost universal prevalence of syphilis among the Southern negroes at least places her under suspicion.

The second case occurred in 1913 in a husky Italian, on whom I did a cholecystostomy. The incision was made through the right rectus muscle. Five days after the operation the incision showed

*Read at the Thirty-second Annual Meeting of the American Association of Obstetricians and Gynecologists, Cincinnati, Ohio, September 15-19, 1919.

no healing and no infection, and the intestines were protruding. He was taken to the operating room, sewed up again, and fed actively on iodides, with the result that his incision healed perfectly. In his case the Wassermann reaction was positive.

The third instance occurred in a patient on whom I did a Wertheim operation for carcinoma of the cervix. The other two patients were strong and robust. This one was of lowered vitality, although the cancer had not progressed extensively. When the skin stitches were removed on the tenth day, the incision presented a straight line of apparently perfect union. There had been absolutely no evidence whatever of infection. A few hours afterward, however, it had all fallen apart, even the peritoneum. The Wassermann test was reported negative, but it was learned that she had conducted for years a number of houses of ill fame, in a series of cities. Her general facies and appearance with sunken nasal bridge and husky voice would have suggested specific disease if there were no such thing as a Wassermann, and there is no doubt in my mind of the presence of an old specific infection, in spite of the negative Wassermann.

These three cases are not enough for definite conclusions, but two were undoubtedly syphilitic and the other was probably so. This evidence is enough to suggest syphilis as one of the causes at least, of delayed healing in the abdominal incision. If by this report I may be able to stimulate the discussion of your individual experiences and to urge each surgeon who may have a few cases, to study them from the viewpoint of specific syphilitic infection and report the results, in a year or two enough data may be collated to enable us to conclude what part old syphilitic infection plays in the absolute lack of healing in incisions in which we had every reason to expect perfect results, primary union and better things.

AN EARLY VIEW OF VENEREAL DISEASE

BY THE HON. WILLIAM RENWICK RIDDELL,
LL.D., F.R.H.S.,

Toronto,

President of the Canadian National Council for Combating
Venereal Diseases.

The terrible prevalence of venereal diseases has been forced upon the attention of the Canadian government and a national council has been formed to assist the central and local governments in combating the evil. As president of this council I was led to examine again what some of the older authorities had to say about these diseases.

From a somewhat extensive collection of ancient medical literature in my library, I select as one of the most instructive and interesting a volume of 516 pages, licensed September 2, 1664, and published in London in the following year. The title of the work is *Medela Medicinæ, a Plea for the Free Profession and a Renovation of the Art of Physick*. The author is given as M. N., Med. Londinensis, the

motto *Medice cura teipsum*. It is known, however, that the author was Marchmont Nedham (or Needham), a versatile journalist (1).

Medela Medicinæ, healing of medicine, is an attack on the formal practice of the physicians of the time. It attacks the Methodists who strictly followed rule, Galenists who care not if a patient die so long as he has been treated *secundum artem* ("Let him die, if he will, so he die *secundum artem*." (2), like Balzac's physician of Mantua, who "did not only not particularly inquire into the cure of diseases but boasted that he had killed a man by the fairest method in the world." The writer urges experiment, the use of the microscope, inquiry of smiths, grooms, farriers, cattle breeders, barbers, midwives, nurses, old women, as to their remedies. Spurning as mere chimeras the old doctrine of four elements attributed to Hippocrates, of four qualities and four complexions fathered by Galen, and also Galen's real "allopathic" principle that "contraries are to be cured by contraries," he himself accepts Dr. Willis's five elements: water, earth, salt, sulphur and spirit (3).

Nedham does not so much find fault with the practice of Hippocrates—he savagely attacks Galen—as try to show that however useful the practice was in Hippocrates's country and time, it was not useful in England in the seventeenth century, and "in plain English a Doctor bred in the Contemplative Philosophy of the Schools may be a Scholar and a very fine Gentleman, but what is that to the Curing of a Disease or the rousing of a Heartsick Man from his bed of Languishment." As an example of a drug with medicinal qualities elsewhere, but not in England, he speaks of "Coffee which Prosper Alpinus (the last of the Methodists) in his book *De Medicina Ægyptorum* relates to have abundance of vertues in that Country of Egypt, of which we find no effect in England save that it serves to make a Liquor harmless enough in Rheumatick Bodies, for ordinary conversation like other Drink but not for any considerable peculiar uses of Medicine as in Egypt."

His main thesis is that diseases have been much changed and that they "are of another nature than they were in former times." The main causes of this alteration he states as being the French pox (4) and the scurvy. It is his account of the former disease which is of interest to us in this connection.

At its first appearance in the world, the French pox was very different from what it had become. Fracastorius (5) and Benivenius (6) tell us that "it in the beginning broke (7) forth in odious pustules of several kinds upon the privates, the head, the face, the neck, the breast, the arms and generally the whole body. Some also it disfigured after the rate of a leprosy; others had a kind of scurf, which scaling off discovered the skin underneath to be black or blue. Upon some, fowl ichorous sores were continually running. And besides all these they had in the inward parts great tormenting ulcerations, as in the mouth, the throat, the nostrils, the urinary and spermatic passages which did eat off the penis, the palate, the lips, the nose in despite of all medicines, so that men being affected with the disease, their friends were frightened from look-

ing upon them and spurned them as if they had been visited with the pestilence. These things being considered with the terrible pains that racked them it was rightly termed by a certain author *Miserabile scortatorum flagellum*."

But Fracastorius, who he observes was born before the introduction of syphilis into Europe, says that in twenty years it altered much and that there was after this another imitation within six years' time, the disease not raging as before in the external parts. This agrees with the account of Fernelius "who was born almost twenty years before it was discovered in Europe and lived to seventy-two years of age, saw it much changed in the space of thirty or forty years, in so much as he tells us in his time it was much altered, not defacing the bodies of men with pustules, scurfs, and virulent ulcers but tormenting them more with intolerable pains which though they might be increased by the ignorant and preposterous ways of curing them used, yet the disease itself also changed continually and seemed to decline and grow old—*adeo ut lues quæ nunc grassatur, vix illius generis esse putetur*" (8).

Two or three generations later Sennertus (9) observed that, whereas in earlier times nearly all if not all infections took place in coition, now "where one person gets this disease by the beastliness of venery, many hundreds have it by traduction," for he says, "The French disease is now become hereditary, being derived from parents to their posterity by generation and communicated from infected persons to others by kissing, by sucking, by clothes and the like."

Nedham points out that the venereal distempers contracted in either of these ways differ externally from that gotten by unlawful contact, for they (i. e., those contacts in any of the ways mentioned) "usually appear in the form of other maladies," for which he vouches not only eminent authors but also his own daily practice "as abundance of people grow sickly and languish under the appearance, it may be, of a consumption (10), a gout, a dropsy, an ague, a slow fever and sometimes an acute one, sore eyes, green sickness and indeed all manner of diseases, which when the other ordinary means have long been used in same, have at length been relieved by an orderly, i. e., systematic, use of antivenerous remedies." He says further: "This disease falls sometimes but gently on the hair, sometimes on the nerves and causes all manner of palsies, cramps, convulsions, toothache, pains in the limbs, gout of all sorts, lameness, general debility, etc.; sometimes on the bones, sometimes on the fleshy parts whence come leprosy, scurfs, ulcers, knotty swellings, and the like; sometimes on the brain, whence come sore eyes, rheums, catarrhs, epilepsies, etc.; sometimes on the lungs, whence come asthmas, coughs, phthisical consumptions, etc., and so many other diseases too long to enumerate." He warns "strikers" (11) of their great danger and says of "women strikers" that there is scarcely any possibility of escaping infection because they are the receivers of impurity. The very carefully prescribed precautions for the "male strikers" are given in the "decent obscurity of a learned language"—Latin. They consist of imme-

diately and thorough ablution preferably with hot water *post coitum*, for while "an internal taint (more or less) be scarce ever avoided by any, yet cleanliness *ex post facto* is a great means to prevent the virulent eruptions of a gonorrhœal exulceration and other sad effects in and about the genitals." Such measures may be quite ineffective *quo flagrantius libidine exardescunt et, equorum instar, igneo spermate stimulati rem ferocius affectant* (12).

One cause of the impossibility of preventing contagion is the supposed fact of contagion at a distance. This our author firmly believes, and quotes learned authors in support. Zacutus Lusitanus (13) says: "I have proved the French pox is contagious at a distance." Minadous (14) considered that he had also proved the same and thought that natural spirits might carry contagions from one to another. Avicenna (15) is authority for contagion at a distance in leprosy, Zacutus in leprosy, scabs, scurfs, itches, sore eyes, catarrhs, etc.; and our author submits that there is no reason why it should not be the case in French pox. He does not indeed accept the theory of Minadous that "natural spirits carry contagion"; he has two other media which he advances explaining them on scientific lines, as science was then understood. True "the ordinary gross conceit (conception) of the world concerning corporeity renders doctrines of this kind very difficult to comprehend; but he who reads the finer philosophy of this wiser age and does not take measure of it by the beards of our ancestors but has digested the principles of the magnetic or sympathetic doctrine of our noble Digby (16) and others treating of the subject . . . of the truth of which daily experiments are a sufficient testimony, will soon agree upon the probability, the certainty indeed, of persons being seizable at a distance by virtue of the continual effluxes of atomical corpuscles which one may call bodikins instead of bodies, whereby the grosser substances, usually termed bodies, are touchable by each other and hold communication with each other at remote distances and so operate upon each other by infection or qualification." The principles are plain and quite in accord with the science of the time. Every body struck by light has small atoms separated from its mass and then the light carries off these atoms, minute corpuscles, "bodikins," these flow with the light or without it, through the air at all times and in all directions and may be attracted by their like or may strike at random. Consequently, as "Fracastorius and Nicolaus Leonicensus" (17) two learned Italians do both contend that the French pox rambles . . . seizing folk that never had any carnal mixture with unclean persons." Fortunately perhaps the disease thus communicated is different in its effect from that caught by carnal intercourse—the latter is usually more visible in its dire effects upon the body by gonorrhœas, buboes, ulcers, etc., while the former "is of a finer nature and dives not so deep at once into the blood and humors (fluids) as it insinuates into the spirits and ferments of the body and acts by time and stratagem, lying still till it has an opportunity, not but that the other many times lurks some years also, but this more curious (18) way of contagion for the most part after it has made entry

proceeds leisurely and gradually to debauch (19) the whole habit of the body and seldom plays the tyrant till it has made a full and final usurpation which it seldom accomplishes without a revolution of many years. And then perhaps it appears not like itself but in the shape of some one or more diseases . . . So in this disease, the pox, may lurk, but the manner how with the reason why, we can only guess at." Sennertus is quoted with approval as saying that the lues passes under the name of many diseases, for the venom lurking in the body though it seems extinct will show itself after thirty years' time. "It will act all the diseases of the stomach, liver and spleen; it will appear in a headache, vertigo, falling sickness, catarrhs and distillations (20) of all sorts, strange arthritical pains, diseases of the lungs and of the womb, etc."

So much for mechanical effluvia. The author is more interesting when he speaks of another source of infection not unlike the former. It is the conception of the famous Jesuit Athanasius Kircher (21) of Fulda, then living at Rome, which Nedham approves. The "new paradox" (22) of Kircher was that contagion was conveyed "not only by the volatility of such effluvia, atoms and corpuscles as were inanimate but by such also as were animate, living creatures, and were a sort of invisible worms or vermicles which were visible only under the microscope. (Had he said bacilli, spirochetæ, or the like, he would have been modern.) Our author says that by the use of his microscope he discovered why sage unwashed is hurtful to those who eat it: for Nedham examined sage with his microscope and found what appeared to be animals exceedingly small on it—he gives a number of other experiments showing the marvel of the microscope and is perfectly satisfied that measles, smallpox, spotted fevers and purples (23) (purpura, petechial fever so-called) come from small worms or vermicles, and does not hesitate to say that much of the infection of the lues is due to these small animals, animalculæ. But more than the terminology is wanting to bring him up to our modern way of thought. He believed these small animals were flying all the time through the air retaining their vitality indefinitely, a conception contrary to our modern science.

As to the treatment and cure of venereal disease, he seems to give full credence to a superstition still prevalent, namely, that one recently infected may get rid of the disease by passing it along without delay to another of the opposite sex. He reprobates the practice indeed, but does not doubt its efficacy. "For at first taking the disease lodges in the out parts, viz., the urinary and spermatic vessels, and doubtless ought to be sent back the same way that it came in, as is evident by the immediate cure that some as soon as they have been clap't have procured to themselves by repeated coitions with sound women: and some I have known to glory in this villainy of debauching that sex in order to bring about a cure."

He has no patience with the do nothing physician and he rightly deprecates the neglect of an infected person "to look out for a cure" and has nothing but condemnation for the custom "to run to any pretender for a cure for pox . . . for the pretend-

ed cure very often proves worse than the disease destroying the constitution." Some physicians are no better "because they make use of the common scope and remedies in curing." He condemns the cheap-poor-whore-cure by fontanels or issues derived from the practice of the poorer Spaniards. Mercurial unguent may serve for "carriers and porters and other robustious bodies" but "setting upon every venereous patient with this dreadful remedy" is unpardonable. The resulting salivation with other dreadful symptoms following its use show that Nedham was speaking of the unguent treatment carried to excess. The mercurial cinnabar fume was yet worse and to those with pectoral troubles it was pernicious for "use what care you can, the mercurial air will get into the chest." Salivation by internal medicine was quite as bad as managed by most surgeons, although it was the best of all ordinary ways—but care should be used to "do the work of salivation without those tedious and intolerable afflictions of swollen head, loose teeth, sore and swollen mouth, tongue and throat, etc."

Keep away from receipt mongers, for the "common sort . . . err not only in their pretended way of curing the pox when it is inveterate and confirmed but they stumble and do as much mischief in the very beginning when it is but a clap (as they call it) a virulent running of the reins, etc." There must be due temperance and rule of eating, drinking, exercise and recreation; but when all is said and done mercurial salivation is the only cure.

I do not here follow the author in his remarks as to the treatment of scurvy and other diseases, or into his animadversions on physicians and their practice in general; these matters are not germane to the object of the present inquiry.

NOTES.

1.—Marchmont Nedham (or Needham) born 1620, educated at Oxford where he took his B.A. at the age of seventeen. He was afterwards an usher in Merchant Taylors' school, then an under clerk in Gray's Inn, of which he became a member in 1652. He also studied medicine, when, where and under whom does not appear. He found his true vocation in journalism. He was a supporter of Cromwell and his scurrility, vigor and boldness were not surpassed in any of the writings of the period. On the restoration of the Stuarts in 1660 he took refuge in Holland but soon obtained a pardon and returned to England. For the rest of his life (he died in 1678) he practised medicine with an occasional excursion into journalism.

My copy of the *Medela Medicinæ* is bound in contemporary calf, not tooled or gilded. It seems to have at one time belonged to a Dr. Mudd (not the Dr. Mudd who looked after Wilkes Booth's fractured fibula and paid so dear for his humanity). Some previous owner had made a memorandum on the page opposite the title page, "There is an answer made to this book by Dr. Spraddin," referring to Dr. Robert Spracklin's *Medela Ignorantiæ*, 1666. There were two other answers, one by Dr. John Twysden, *Medicina Veterum vindicata*, 1666, and the other by Dr. George Castle in *Reflections on a Book called Medela Medicinæ*; printed with *The*

Chymical Galenist in 1667. Nedham himself says, "Four champions were employed by the College of Physicians to write against the book," and adds that two died shortly afterward, the third took to drink and the fourth asked his pardon publicly. See D. N. B., Vol. XL, Pp. 159-164: Athenæ Oxon. Vol. iii, 1187.

2.—This reminds one of the skit on the well known Dr. Lettsom, who flourished in London toward the end of the eighteenth and the beginning of the nineteenth century. One very usual form runs:

"When patients sick to me apply
I physics, bleeds, and sweats 'em;
If after that they please to die,
What's that to me?" I. LETTSOM.

3.—Dr. Thomas Willis (1621-1676), M.A., Oxford 1642: M.B. 1646: M.D. 1660: F.R.S., F.R.C.P. 1664. He was the first to distinguish diabetes mellitus and was physician in ordinary to King Charles II.

4.—Nedham calls this disease by many names—pox, French pest, French disease, French ferment, French pox, pocky disease, pocky lues, pocky ferment, pocky infection, lues venerea, lues, French lues, French infection, venereal disease, venereal distemper, never syphilis. Gonorrhœa is mentioned but, of course, it was then supposed that gonorrhœa was a form of pox, an error which was later confirmed by Dr. John Hunter's classic experiment on himself and which gave way only after the investigations of Ricord and his school. Neisser, of Breslau, placed the specific identity of gonorrhœa beyond question in 1879 by his discovery of the gonococcus: but it was not till 1905 that Schaudinn and Hoffman identified the *Spirochæta pallida* of syphilis.

5.—Girolamo Fracastoro (latinized Fracastorius) 1483-1553 of Verona, physician to Pope Paul III: he revised the old theory of "critical days" and rather gave it a new lease of life. It was in full vigor in England in Nedham's time and is attacked by him. Fracastorius, among many other works, medical and poetical, wrote a book on *Contagious Diseases* but is best known by his famous poem *Syphilidis sine Morbi Gallici libri tres*, Verona, 1530, often reprinted and translated into French and Italian. (The Latin form is very rare, I have seen only one copy.) The hero of the poem was a swineherd, Syphilus, i. e., the swine lover (without apparently any implication of unnatural vice, although that form of crime has been not infrequently suggested as the original of syphilis) and his sufferings from the *Morbus Gallicus* were the theme of the poem. The Italians charged the French with being the originators of the infection, whence *Morbus Gallicus*, while the French not to be behind in international courtesy gave the honor to the Italians, whence *Mal de Naples*. The almost universal use of the term syphilis seems to be largely due to Sauvages—Francois Boissier de la Croix de Sauvages (1706-1767) the animistic mechanician who made a system of diseases on the lines of Linnæus' System of Botany in his *Nosologia Methodica*. Sauvages makes ten classes of diseases, 295 genera, and 2,400 species. (Linnæus had 325 genera of plants).

6.—Antonio Benivieni (ob. circ. 1502), of Flor-

ence, a Hippocratic of a somewhat rigid school. He is of some note as an obstetrician and pathologist.

7.—I modernize the spelling, capitalization, punctuation, etc.—archaisms in these are apt to draw the attention away from the substance. There could not be said to be a standard English orthography until Dr. Samuel Johnson's time, every one following his own judgment, taste or caprice and not infrequently two or more spellings of the same word would be found by the same author in the same book, the same paragraph, sometimes in the same sentence. Capitalization did not become thoroughly standardized until well into the nineteenth century—often the nouns were written with a capital as is the custom still in German; other important words were often capitalized while adjectives generally received a small letter as in French.

8.—Jean Francois Fernel (Fernelius) was born in 1497 by which time syphilis had been recognized in parts of Europe. The celebrated siege of Naples by Charles VIII of France which was the cause or at least the occasion of spreading the infection took place in 1495. But Nedham gives his age at death as seventy-two; Fernel died in 1558, therefore Nedham must have thought that he was born *circ.* 1486, and indeed 1485 is given as his birth year by some authorities, e. g., Bass in his *History of Medicine*. Fernel was a great mathematician but turned his full attention to medicine at the age of thirty-five; he was the most distinguished physiologist of his age but thought the blood originated in the liver and the "elements" were actual bodies. Nedham quotes from Fernel's *De Lue Venerea* and part of his work *De abditis rerum causis*. The Latin with which the quotation ends means: "So much so that the lues which now prevails can hardly be considered of the same kind."

9.—Daniel Sennert (Sennertus) 1572-1637, the son of a shoemaker in Breslau, studied at Wittemberg where he received his degree in medicine, Leipzig, Jena, Frankfort and Berlin. He became a professor in Wittemberg and introduced the study of chemistry in that university. He died there of the plague in 1637. He was one of the first to describe scarlet fever (1619); he was an "atomist" and held that each element had primary particles, corpuscles or atoms peculiar to itself. His works are in six large folio volumes, the last edition published at Lyons in 1696; the quotation is from Book VI, part IV, chapter 5.

10.—It must be borne in mind that consumption until very recently had a wide connotation. See Note 7 to my article in the NEW YORK MEDICAL JOURNAL of September 27, 1919, on Medical Theory and Practice of an 18th Century Doctor of Divinity. Nedham himself speaks of three species, hectic, phthisic, atrophic.

11.—This word is no doubt akin to the German Streicher; while it was not in very common literary use before and at Nedham's time it had been used by Nash and some others. The New English Dictionary, p. 1136 *sub voc.* Striker 2 d quotes this very book *Medela Medicinæ* for its use. The word is synonymous with *scortator* or what Nedham bluntly calls whoremonger. A woman striker is the female of the species.

12.—“Where they are too passionately inflamed with desire and, like horses, urged on by burning semen attempt their aim too fiercely.” The precautions to be taken are given in Latin “locked up from the eyes of common readers partly for modesty’s sake and partly because such cautions may prove an encouragement to wickedness.” The reasons for avoiding all reference to such diseases and prophylactics against them are only now beginning to yield to terrible necessity. Zacutus Lusitanus (Abraham Zacuto), 1575-1672, a learned Portuguese Jew born in Lisbon, an ardent follower of Galen and the Arabians and a pathologist of some merit, is quoted for preventive rules but even Zacutus admits their failure in some cases.

13.—See Note 12. The works of Zacutus cited are his *Praxis admiranda*, Book II, obs. 134; and *De Medicinæ Principalium Historiæ* 73.

14.—Thomas or Aurelius Minadous, 1554-1604, a celebrated practitioner and professor at Padua, one of Harvey’s preceptors—the work of Minadous cited is *De Lue Venerea*, Chap. V.

15.—Avicenna (Ebu Sina, Abu Aliebu Abdallah ebu Sina) 980-1037, “the Prince of Physicians,” too well known to require further notice here.

16.—As to Sir Kenelm Digby and his powder of sympathy see my article in the NEW YORK MEDICAL JOURNAL for February 19, 1916.

17.—Nicholas Leoniceus (1478-1524) was the first to write on anything like modern lines on syphilis (1497); he was well acquainted with the symptoms and many of the effects of the disease which he considered infectious and epidemic: he did not believe in the American origin of the disease but thought it had existed in antiquity. He was a fine classical scholar and occupied with lustre the chair of medicine at Ferrara. He was largely responsible for the reinstatement of Hippocrates and the loss of influence of Pliny.

18.—“Curious” in the seventeenth century had certain meanings now rare or obsolete; it means here ingenious, clever.

19.—“Debauched the whole habit of body”—“debauched” was a new word in English at that time, having been imported from France about 1600—the French *débaucher*—it meant corrupt or pervert: “habit of the body” was the same as our late “diathesis,” *valde defendus*.

20.—“Distillations” are fluids forming in minute drops from any tissue—not distinguishable from catarrhs except that the catarrh is rather flowing and *en masse*, the distillation stationary and minute.

21.—Athanasius Kircher, (latinized Kircheus), 1601-1680, entered the Jesuit order at the age of seventeen; he became almost an Admirable Crichton. He lectured at the University of Wurzburg on philosophy, mathematics, Hebrew and Syriac, afterward he taught mathematics and Hebrew at Rome, where he died. He was one of the first to study the hieroglyphics of Egypt. It is his work *De Peste* which Nedham makes use of; it was written in 1658 and afterward printed at Leipsic with a preface by John Christian Lange.

22.—“Paradox” in the proper and etymological sense of an opinion opposed to that commonly held. cf. De Morgan’s *Budget of Paradoxes*.

23.—Nedham says that Drs. Lange and August Hauptman even before Kircher’s investigations were troubled over “that terrible disease, the purples, which so frequently befalls women within the month after childbearing” and laid their heads together to determine the cause. They found under the microscope petty vermicles spread upon the whole superficies of the characteristically rough skin and concluded them to be the cause. It is perhaps better not to know things than to know things that are not so.

24.—We know that Lange ascribed syphilis to microscopic worms and Hauptman to small insects—a mere difference in terminology.

OSGOODE HALL.

DISORDERS OF FUNCTION OF THE URINARY BLADDER.*

BY SERGEANT PRICE MARTIN, M. D.,
Buffalo, N. Y.

The function of the urinary bladder is to act as a reservoir for the urine received from the renal ducts and to retain it until discharged through the urethra. After the completed act of urination the bladder under normal conditions is empty, its walls being retracted to their full extent. As urine flows in from the kidneys the walls gradually relax to accommodate the fluid, so that the internal pressure remains at a constant level. The extent to which the walls can relax depends on the individual bladder and whether its walls are healthy or in a state of disease. At any time, however, if the attention of the brain is called to the bladder a feeling or desire to evacuate the bladder may be induced, which desire also can be set aside by will if the attention is diverted from the bladder, but at last a condition is reached when the bladder walls have relaxed to their fullest extent and then they begin to undergo slight tonic contractions. If the call is neglected long hypogastric pain is felt, continuous and spasmodic, and finally the desire to micturate becomes uncontrollable.

The call to micturate under normal conditions is largely a matter of habit. The normal bladder can be trained to retain urine for many hours or it can be made to fall into bad habits through nervousness and ability to gratify the desire readily and often. Various foods and drinks have a profound influence. Urine of a high density containing much pigment and uric acid in suspension can often be held for hours, whereas urine of low density may have to be passed every hour or oftener.

The muscles of the bladder consist of two sets: The detrusor set, consisting of longitudinally and circularly disposed smooth muscle fibres, and a sphincter set, consisting of the muscles of the trigone and circularly disposed smooth muscles at the entry of the prostatic urethra. The muscles are under voluntary control to a certain extent, that is to say, the whole complex act of micturition can be started or stopped by means of voluntary impulses descending from the brain but beyond a certain limit the brain ceases to be able to control them

*Read before the Buffalo Academy of Medicine, April 7, 1920.

and micturition becomes involuntary and forced. The compressor urethra is a voluntary muscle which can be used as a sphincter of the bladder and in addition there is a set of voluntary muscles which can be made to empty the bladder by increasing the general abdominal pressure, namely, the muscles of the belly wall and the diaphragm.

The involuntary muscles of the bladder are supplied by two sets of nerves: sympathetic fibres from the hypogastric plexus which run out from the cord along the lumbar nerves; sympathetic fibres from the sacral plexus which run out along the second and third sacral nerves forming the nerve erigentes. Stimulation of the hypogastric nerve endings produces inhibition and relaxation of the detrusor fibres and contraction of the sphincter fibres. Stimulation of the nerve erigentes produces inhibition and relaxation of the sphincter and contraction of the detrusor.

During the act of micturition the sphincter is relaxed and the detrusor contracts. The act can be stopped, however, voluntarily by contraction of the compressor urethra till the inhibitory impulses to the involuntary muscles have time to act, or urination may be stopped by disease of the coordinating nervous mechanism.

The following disorders of the bladder will be briefly discussed: Inflammations, tumors, vesical calculi, atony, hypertrophy, and nervous disorders.

INFLAMMATION OF THE BLADDER.

The inflammations of the bladder may be reduced to a small number of clinical types, though each of these types has many variations. Authorities differ so widely in their classifications of cystitis that an accepted classification can hardly be said to exist. The following simple classification, however, will suffice to illustrate: 1, Nonbacterial cystitis, a, traumatic, b, chemical; 2, simple bacterial cystitis which may be acute or chronic, acid or alkaline; 3, tuberculous cystitis.

Traumatic cystitis.—A mild cystitis or irritability of the bladder as it is often called may be caused by the passage of a highly concentrated urine containing phosphates, urates and oxalates. This is characterized by more or less frequency of urination and distress. The so-called gouty or rheumatic cystitis is of this type.

Chemical cystitis.—Any strong irritant entering the healthy bladder whether from the kidneys or through the urethra may cause a cystitis. Rehm and Lichtenstein (4) have called attention to marked vesical tenesmus occurring in coal tar workers, apparently due to inhalation of irritating vapors. While hyperacid urine is irritating to the bladder, ammoniacal urine is far more so, and the reason why an alkaline cystitis is likely to be so much more intense may be due to the fact that the ammonia adds fuel to the fire of bacterial attack. Cystitis may equally be caused by irritants introduced through the urethra. Nitrate of silver is so often used in a concentrated solution that it bears an unenviable notoriety in this regard.

Simple bacterial cystitis.—This is the disease that is generally spoken of as cystitis.

Acute bacterial cystitis.—This is characterized by a sharp congestion most marked around the trigone

and the neck, or it may be entirely confined to that region. The mucous membrane is swollen and bright red in color. The capillaries are dilated, the epithelial cells swollen. Later the epithelial cells begin to desquamate. Then the angry crimson of the mucous membrane is blotched by petechiæ, its gloss is lost and here and there minute vesicles or abscesses may appear. After these break, small ulcers remain. If the acute condition persists the muscular and peritoneal coat become inflamed.

Chronic bacterial cystitis.—The mucous membrane is irregularly thickened and dense. Its surface may be red or gray in color, while here and there may be seen areas of ulceration or granulation.

Frequency of urination is the constant symptom of cystitis except in mild cases or where there is retention or suppression of urine. It is a fair index of the severity of the inflammation. In mild cases the patient may urinate every three hours or so during the day and empty his bladder only once or twice during the night. On the other hand, a patient suffering from acute cystitis may urinate with great frequency during the day and night, the calls to urinate occurring every ten to fifteen minutes and if they are not obeyed they result in the expulsion of the contents of the bladder no matter how much the patient may strain to retain the bladder contents. Frequency of urination, however, is by no means pathognomonic of cystitis, it may be purely neurotic or may be due to prostatitis, hypertrophy of the prostate, vesical calculi or other causes.

Vesical pain in cystitis is due as a rule to the presence of urine in the bladder. If there is no retention the pain is intermittent. If there is retention the pain is constant. It is most severe at the time of urination. In mild cases it may only be felt at that time. It is felt chiefly in the glans penis and the perineum though it may radiate along the under surface of the penis up the rectum to the hypogastrium, groin, hip, testicle or loin. When the inflammation is marked there is often a continuous ache in the perineum, the hypogastrium or the hip, while in dysuria there may also be an irritating spasm of the bladder and its sphincter as the last drops of urine are passed. The patient straining after the bladder is empty markedly adds to the irritation already present.

Although patients suffering from cystitis often exhibit such symptoms as chills, fever, sleeplessness, anorexia and loss of weight and strength, these symptoms are not necessarily directly referable to inflammation of the bladder, but may be due to inflammation of the prostate gland or to involvement of the kidneys, or may be the result of the distressing symptoms of pain, dysuria and tenesmus.

Chronic cystitis is so common that there are few diseases of the lower urinary passages of which it does not form a part of the picture. Chronic cystitis rarely commences as an acute disease but is chronic from the start. Once started it does not tend to get well spontaneously but slowly and steadily becomes worse. Fortunately its causes are well known and most of them easy of demon-

stration. Many of them can be removed and with them the chronic inflammation which they keep up. Some cases are incurable on account of permanent structural alterations that have taken place in the bladder walls or because the cause cannot be reached. All, however, may be benefited by careful study and judicious management in the hands of a skilled urologist.

Tuberculosis of the bladder.—The characteristic irritability of the bladder, the frequency of urination and the pain accompanying the act is often the earliest and always the most distressing symptoms of tuberculosis. At first the frequency of urination is not so great although there may be marked discomfort, as soon as a few ounces of urine have collected in the bladder, and the pain is chiefly confined to the end of urination. As the bladder contracts down on the last drops of urine a terminal hematuria may appear and a sharp pain may be felt in the perineum and often on the under surface of the penis at the penoscrotal angle. The effect of this pain is to excite a tighter spasm of the bladder and the result of this spasm is an increase in the pain so that a good deal of pain and spasm persist after the last drops of urine have been voided. This will leave a soreness which may not pass off before another urinary act renews the distressing cycle. At first this pain is only fairly constant but later accompanies every act of urination.

As the disease progresses ulcers are formed or mixed infection occurs, then another pain may be felt, a pain before urinating, characterized by an irresistible urgency, which if not immediately gratified may result in a spurt of a few drops of urine down the sufferer's thigh in spite of all his efforts to prevent it. The urine of tuberculous cystitis is acid. At first it may be clear or bloody. Later it is bloody and often foul with products of suppurative cystitis. But however foul and ammoniacal it may be, its one striking characteristic is its continued acidity. However, it is not impossible for the urine of a mixed infection to be alkaline when passed as a result of the predominance of pyogenic cocci. The most important part of the urinary examination in this type of cystitis is the search for and finding of the tubercle bacillus.

TUMORS.

The majority of the tumors of the bladder are of epithelial origin. The tumors generally begin as benign papillomatous growths but soon undergo carcinomatous degeneration. Next in frequency come the connective tissue growths fibroma, myxoma, sarcoma and the mixed tumors. No more is known about the pathogenesis of tumors of the bladder than about tumors occurring elsewhere. In the report of ninety-nine cases of bladder cancer collected by Nason, seventy-eight occurred in men. From this we are led to believe that the condition is met with at least twice and perhaps three times as often in men as women. Tumors may occur at any age, but the majority of carcinomata occur in the decades between thirty and sixty.

The first, the last and often the only symptom of a tumor of the bladder is hematuria. As a rule the more villous the tumor the more profuse the

bleeding. The characteristic hemorrhage of a neoplasm begins without apparent cause or warning, may last for several days, be copious and painless, unaffected by rest, diet or medication, and cease as suddenly as it began without any apparent reason. Its cessation may leave the urine entirely normal and the patient is lulled into a false sense of security by what he considers his narrow escape from a perilous condition. A profuse hemorrhage of this type is almost pathognomonic of neoplasm. Though it may assume any form the hemorrhage usually grows more severe and recurs more frequently as the disease progresses.

Of all the instrumental manipulations employed in the diagnosis of tumors of the bladder, cystoscopy stands first, for it alone indicates the presence, the nature, as far as can be determined, the location and the number of tumors.

VESICAL CALCULI.

Single calculi are generally rounded or ovoidal in shape. Multiple calculi are usually phosphatic, less frequently uratic. In general their number bears an inverse relation to their size. There are no symptoms absolutely and invariably pathognomonic of stone in the bladder, yet there is a certain group of symptoms which are very suggestive of stone. Chief among these are frequency of urination, pain and hematuria, occurring by day and increased by exercise. The pollakiuria and dysuria of stone are usually intensely marked and appear early in the disease. The pains are situated chiefly in the glans penis along the pendulous urethra and in the perineum. The characteristic distress is absent during the night or when the patient lies quietly on his back. Many different ways have been suggested to prove the existence of stone in the bladder. Among these the cystoscope and x ray are the most popular today.

ATONY OF THE BLADDER.

Loss of bladder power may be due to disease of the muscle fibres themselves rather than the nerve supply. A state of atonic relaxation may be produced which is so complete that there is passive distention of the bladder with continual passive overflow or it may be incomplete, the muscle fibres being unable to retract to their full extent.

Atony of the muscle fibres is produced by the following causes: 1. Mechanical overdistention, a, after a single acute unrelieved retention, b, insidious onset from chronic back pressure. 2. Poisons acting on the muscle itself, a, acute specific fevers, especially typhoid and influenza, b, chronic cystitis (diffuse fibroses of the wall). 3. Poisons acting on the nerve supply and the muscle, belladonna and morphine.

It used to be held that if the muscle of the bladder became atonic no recovery of tone would take place. From observations of the end results of prostatectomy it is becoming increasingly clear that recovery of tone can be expected and may even be complete if the cause is removed, especially if caused by urethral obstruction. Drugs such as nuxvomica are useful adjuvants, and the muscle can also be exercised by applications of the triphasic electric current to the hypogastric.

Hypertrophy of the bladder is the result of an

obstacle to the free flow of urine through the urethra. The commonest causes of obstruction are enlargement of the prostate gland and stricture of the urethra. It may however be caused by severe prolonged inflammation with but little obstruction (vesical stone or vesical tuberculosis). There are no special symptoms of vesical hypertrophy except frequency of urination. The treatment of hypertrophy of the bladder is the removal of obstructive and inflammatory causes.

NERVOUS DISORDERS.

One of the first and often the first sign of tabes is a bladder that functions badly. A tabetic bladder crisis generally begins suddenly towards the end of micturition. As the last drops of urine are squeezed out an intense cramping pain is felt in the urethra and at the end of the penis. The pain passes off in a few minutes but in a short time the desire to urinate returns and the attack is then repeated. The intervals between attacks may vary from a few minutes to hours or days. The pain usually is so intense as to cause the patient to double up and cry out. These pains presumably take origin in the degenerating neurons and as degeneration becomes complete the pains pass away and do not return. The patient then passes into the stage of painless paralysis. These crises, however, are rather the exception than the rule in tabetic cases and the patient may have little or no pain from the onset.

In the early stages the coordination of the act of urination is interfered with, the sphincter hesitates to relax as the detrusor contracts so that sudden interruption of the stream occurs or the urine drips away slowly. In a later stage there is a partial retention of urine with increased frequency of micturition. The detrusor becoming relatively insufficient, the bladder is neither full nor ever completely empty, a residual urine varying from six to twelve ounces may be removed by a catheter. This stage gradually passes into one of complete retention with overflow and incontinence but as the sphincter is relaxed the mere act of coughing or any slight straining movement may produce a dribble of urine. In considering diagnosis the nature of the nerve lesion must be determined and suitable treatment applied, especially if there is a syphilitic taint and the exact condition of the bladder should be investigated by means of the cystoscope.

This paper is presented in the hope that a better cooperation may be arrived at between the general practitioner and the urologist in diagnosing and treating lesions of the genitourinary tract.

Acute Endaortitis with Formation of Two Aneurysms and Rupture of the Aorta.—F. Merke (*Schweizerische medizinische Wochenschrift*, February 12, 1920) reports the case of a man fifty-one years old, suffering from chronic cystitis, in whom an aortitis developed. This was followed by the formation of two aneurysms of the aorta and final rupture. The aortitis was ascribed to a bacteriemia arising from the urinary passages.

THE WASSERMANN REACTION.

By CHARLES GREENE CUMSTON, M. D.,
Geneva, Switzerland.

The subject of Wassermann's reaction is still under discussion and in the remarks which are to follow I shall borrow freely from the work done by Golay and others at the syphilographic clinic of the University of Geneva, based on some four thousand five hundred reactions. Negative in all subjects free from syphilis, Wassermann's reaction must necessarily become positive after infection since, without exception, every person with florid specific secondary lesions as yet untreated will give a positive reaction.

The date of the appearance of the reaction, after the onset of the initial sclerosis, varies with different observers and with the subjects, as Golay has been able to show, since he has had cases of chancre positive on the fifth day after its appearance and others negative as late as the thirty-second day, but after this time the results have been invariably positive. Consequently it sometimes happens that in some cases recent syphilitic chancres give a positive reaction while in others the chancre may have undergone cicatrization and the Wassermann still remain negative, which explains the varying percentage of positive results obtained by different observers during the primary phase of the infection:

Levaditi, Laroche, Yamanouchi.....	46 per cent.	
Wassermann, Citron, Blaschko, Brulius...88 to 91 per cent.		
Gaston and Mauriac.....	79 to 81 per cent.	
Ejowsky ..	} Clinic of Geneva.....	
Pribilsky. }		69 per cent.
Golay.... }		70 per cent.
		76 per cent.

Statistics, to be sure, are of only relative importance because they comprise reactions made at periods more or less distant from the date of the infection. The same statistics made three days after the first appearance of the chancre should give one hundred per cent. negative results, according to Golay's researches, and if done on the thirteenth day in all untreated cases of syphilis, they should give one hundred per cent. positive results. What is still more interesting and useful from the viewpoint of practice is to establish the average date of the appearance of Wassermann's reaction. Evidently it must be positive when, the infection having become generalized, it can be detected in the blood. The septi-cemia, as Gaucher has shown, always precedes the secondary lesions, so that if we take the appearance of the chancre as a starting point, by combining the figures given by different observers, we can place it at about the fifteenth to the twentieth day. By following his patients in series and making a daily examination—the only proper method to follow—Gaucher noted that the reaction became positive in the average case on the fifteenth to the twentieth day. Here are some figures:

Jadassohn (Berne).....	fifteenth to twenty-fifth day.
Oltramare (Geneva).....	fifteenth to twentieth day.
Audry (Paris).....	twenty-fifth day.
Finger (Vienna).....	} twenty-first day.
Wassermann (Berlin).....	
Troisfontaines	twenty-fifth to thirty-fifth day.

It would appear the more sensitive the antigen, the earlier will the reaction be positive, and in point of fact, Desmoulières, using his reinforced antigen,

found that the mean date of appearance of the reaction was between the eleventh and the thirteenth day. Contrary to what has been maintained by others, it would seem to result from this fact that the antibodies do not appear suddenly in the blood, but are produced little by little, and can be detected only at the moment that their quantity corresponds to the sensitiveness of the antigen. As Joltrain and others have pointed out, the septicemia develops earlier following chancres of the lips than of the genital organs.

From these figures it results clinically that so long as a chancre has not fifteen, or even in some rare cases thirty-two days' existence, the seroreaction may not agree with the diagnosis; hence the conclusion that the clinical signs of chancre, the incubation period, the local lesion, adenopathy and above all the presence of the spirochetes, have a far more considerable importance than Wassermann's reaction. On the other hand, the latter may render real help in cases where cicatrization of the chancre has already taken place or is undergoing repair, in which it is no longer possible to find the spirochete nor decide upon its nature until the secondary lesions develop. A distinctly positive reaction will settle the question and intensive treatment be instituted at once.

The seroreaction during the period of chancre, however, will be of interest if it can be proved, as some observers maintain, that abortion of the infection is easier to obtain with the arsenical products while the seroreaction is still negative. Yet in spite of a large number of cases Golay and others of the Geneva school are not prepared to offer a positive opinion in this respect.

All untreated cases of secondary syphilis will give a positive reaction. Nevertheless, from the viewpoint of the diagnosis, the reaction has not at this time a primordial value, since the nature of the lesions, the still visible cicatrix of the initial sore, the inguinal adenopathy, etc., will, in the vast majority of cases, make the diagnosis only too evident. A Wassermann reaction will then only confirm the nature of the disease, but from the viewpoint of the clinical value of the Wassermann reaction a positive result will, on the contrary, be of great importance, since it proves that all syphilitics, unless they have received energetic treatment during the primary phase, have had at a given time a positive Wassermann. At this time also, the reaction has another scientific and clinical point of interest. I refer to those cases where the differential diagnosis between chancreform syphilides and reinfection is doubtful. A positive reaction before the fifth day following the appearance of the chancre is positive proof that the lesion is merely a recurrence and not a new infection.

The percentage of one hundred afterward decreases as time goes on, with the disappearance of the lesions and especially with treatment, which, perhaps, explains the sixty, seventy, eighty per cent. positive results in secondary syphilis obtained by some observers, and frequently comprising all categories of patients, treated or untreated, with or without lesions. In this respect Mauriac has given statistics of the results obtained by

the Wassermann in untreated cases of syphilis as eighty-eight per cent. and fifty-four and one half per cent. in treated cases, but he does not state if in these cases the patients had or did not have lesions present. On the contrary, Ledermann, in his statistics, classified the results in positive Wassermann reactions in secondary syphilis with symptoms as ninety-eight and one tenth per cent. and sixty two and one half per cent. in latent cases, but he does not refer to the question of treatment.

By classifying the cases of secondary syphilis into syphilis with lesions and syphilis without lesions (latent), Golay presents the following results:

Secondary syphilis with lesions, untreated.....	100 per cent.
Secondary syphilis with lesions, treated or untreated	89 per cent.
Secondary syphilis with lesions treated.....	79 per cent.
Secondary syphilis without lesions, treated....	47 per cent.

It will be noted that in the table given above untreated secondary syphilis without lesions does not appear, which would have been highly interesting, inasmuch as it would fix our opinion of the state of the reaction in patients left to their own devices. But these cases which unquestionably exist can only be detected indirectly, when lesions develop a long time after infection, for the simple reason that a subject, who believes himself to be in perfect health and without any specific lesions, will naturally not consult a syphilologist. However, Golay has found that syphilitics who have had little or bad treatment usually present a positive reaction for a long time and he has found that syphilitics of thirty or thirty-five years' standing, subjected to more or less treatment, but who nevertheless had never presented manifest lesions and enjoyed excellent health, presented very positive Wassermann reactions.

These data would seem to confirm the opinion of a large number of syphilographers that clinically, syphilis left to itself will never be recovered from and that although it leaves the patient with remissions of thirty, forty or more years, the presence of a positive seroreaction proves the existence of latent foci at any time ready to become active. Cases of general paresis with a negative Wassermann, far from invalidating this fact, prove that the foci may undergo their evolution in a closed area, so to speak, without influencing the composition of the blood.

During tertiary syphilis, the Wassermann would at first sight seem to offer no rules whatever. For example, it may happen that a subject with a tertiary lesion, whose clinical diagnosis leaves no doubt, may nevertheless give a negative reaction, even when little or no treatment has been followed in the past. But it is probable that such instances are rare, since several conditions may explain this situation, namely, the effect of former treatment or the localization of the process in the central nervous system. In the latter case the reaction is often negative, while Gaucher, Paris and Sabaréanu, studying the seroreaction in twenty cases of incompletely treated tertiary syphilis, obtained four negative results; in three, the central nervous system was involved, while the fourth presented no lesion.

On the other hand it may happen and this is by far more frequent, that a very positive Wassermann coincides with a syphilis which has been latent for

many years and all these data which surprise us and are most confusing may nevertheless find their explanation. If one is dealing with the paradoxical case of an active syphilis with a negative Wassermann and the syphilis is mild, it may be admitted that the treponemæ being localized in one or several foci have lost their activity and do not secrete sufficient toxin for the tissues to react by the manufacture of antibodies, or perhaps that these antibodies, for unknown reasons, are destroyed as fast as they are produced. If the syphilis is severe, it must then be admitted that the organism is too weakened to react by producing antibodies. The same phenomenon is met with in tuberculosis, because, generally speaking, a mild tuberculosis reacts much better to tuberculin than a rapidly progressing caseous tuberculosis.

If, on the other hand, one is dealing with yet another paradoxical condition but of an inverse order, that of syphilis without lesions but with a positive Wassermann, two contingencies may take place theoretically: either the lesions exist but are unnoticed by both patient and physician, or they do not exist and it may be admitted that the spirochetes secrete toxins and produce antibodies by *contrecoup*, without producing any lesion. But now if factors, often badly understood, come into play lesions develop consequent upon the awakening and the pullulation of the treponema which had been until then well tolerated by the subject.

The transformation of a positive into a negative reaction by treatment is explained by the complete or partial destruction of the parasite. The secretion of toxins is then arrested or greatly eliminated, the tissues no longer react or react insufficiently for the antibodies produced to be detected by the seroreaction. An interesting fact has been demonstrated by Iversen and brought to light by Milian, who has even derived from it a very interesting diagnostic and therapeutic proof, namely, that before disappearing the reaction passes through a maximum which coincides with the bacterial lysis. At this moment destruction of the parasites is massive and the toxins they contain are then liberated in the blood in great quantity. This fact can also be compared with what takes place in tuberculosis where, according to Gougerot and Troisier, the microbe dies in a state of solubility and may be more toxic than the living bacillus.

A statistical study of Wassermann's reaction in the tertiary phase of syphilis undertaken by several syphilographers has given quite constant results. Joltrain found from eighty per cent. to ninety per cent. positive reaction; Bruch and Stern, in a total of 378 cases, found it positive in 57.4 per cent.; Bering, in a total of 391 cases, found it positive in 82.2 per cent. and Bayet seventy per cent. These slight variations from one observer to another are to be explained by the fact that they did not take into consideration when making their statistics, either the treatment or the activity, or on the other hand, the latency of the syphilis presented by their patients. In order to obtain a distinct idea of the question the cases should be divided into four classes: 1, patients with tertiary syphilis in activity and not treated; 2, patients with tertiary syphilis in activity

and treated; 3, patients with tertiary syphilis in latency and not treated; 4, patients with tertiary syphilis in latency and treated.

In practice such a classification is impossible, as classes one and three would be wanting. Today, patients coming without having been treated during the secondary period are becoming more and more rare, so that in the present circumstances we must be content with two categories, first, tertiary syphilis with lesions, and secondly, tertiary syphilis without lesions. In parasyphilitic affections, the Wassermann reaction gives quite as high a percentage, if not higher, of positive results of tertiary syphilis. But in these cases, as in those of cerebral and medullary lesions of luetic origin, the examination of the cerebrospinal fluid should always be done at the same time. Their combined study will be of immense help and when the Wassermann is negative the cerebrospinal fluid will be positive, especially when gross meningeal lesions exist.

All observers have noted the fact that the reaction of the cerebrospinal fluid may be positive while that of the blood is negative. Jacobsthal says that is especially true of recently developed parasyphilitic processes, but that later on in the evolution of the process the blood will also give a positive reaction. Therefore, in order to detect general paresis or locomotor ataxia at their very onset a Wassermann and a cerebrospinal test are of utmost importance. Here are some of the results obtained with the cerebrospinal fluid:

Levediti and Marie, positive results.....	80	per cent.
Beaussart, positive results in tabes and general paresis	90	per cent.
César, positive results in tabes and general paresis	78	per cent.
Lesser, positive results in general paresis....	100	per cent.
Lesser, positive results in tabes.....	96	per cent.
Mauriac, positive results in general paresis...	80	per cent.
Ledermann, positive results in general paresis	96.9	per cent.
Ledermann, positive results in tabes.....	76.4	per cent.

For such striking results comment is unnecessary. In hereditary syphilis Wassermann's reaction is no less important and its results are no less encouraging than in other luetic manifestations and may be compared to those obtained in the acquired form of the infection. Demanche and Detre state that in early hereditary syphilis and during its evolution positive results are obtained in 87.5 per cent. of the cases; Mulzer and Michaelis, in ninety-five per cent.; Bauer in 100 per cent. and Bertin and Gayet in ninety-eight per cent., but in late hereditary syphilis the percentage of positive reaction is very much less. Knoepfelmacher and Lehndorff are likewise of this opinion. The two last named observers state that the Wassermann is invariably positive when the hereditary syphilitic infant presents cutaneous lesions, otherwise the reaction is often negative, becoming positive only when lesions appear. It then remains after treatment for many years, regardless of the absence of any lesion. On the other hand, Paris and Desmoulière have shown that in hereditary syphilis the reaction at first positive, later on becomes negative, even when the patient is untreated, an opinion based on a very large number of cases, and what goes to show that the hereditary form has a tendency to cure, even without treatment, is that these subjects may contract syphilis late in life.

THE SCARLET FEVER MYSTERY.

The war has assisted in unravelling some of the tangled skeins of disease, although perhaps none of these has been completely unravelled. Some light has been thrown on cerebrospinal fever and possibly on that form of pneumonia generally known as septic pneumonia. Instructive light is thrown on infectious diseases in England and Wales by the second report of the Ministry of Health on the Incidence of Notifiable Infectious Diseases in each Sanitary District of England and Wales During the Year 1919. Especially is this the case so far as scarlet fever is concerned. The figures show that as soon as the war began the rate of incidence of this disease went down until in 1917 it reached 1.44 to the thousand population. The same rate stood in 1918, but in 1919 it went up to 2.23 a thousand. In 1914 it stood at 4.38 a thousand. Moreover, the death rate from the disease in 1917 and 1918 was described in the Registrar General's return as the lowest recorded in England and Wales; the mortality being trifling compared with that prevalent a generation earlier.

While the scarlet fever rate dwindled during the war, the rate for cerebrospinal fever increased by leaps and bounds. The figures for cerebrospinal disease rushed up from 0.01 to 0.08 a thousand in 1915 and remained high up until 1918, when there was a sharp fall. Why then when scarlet fever was going down, was cerebrospinal fever rushing-up? Dr. Hamer, the Medical Officer of Health for London, believes that there is a connection between scarlet fever and fleas. The war, by moving the population from

place to place and cleaning a portion of it not usually cleaned, may have cut down the flea population. Dr. Hamer reports fewer beds flea marked in common lodging houses during the war period. This view has not been substantiated, but, at any rate, the hypothesis is a plausible one and it is more than likely that increased cleanliness may have reduced the number of fleas throughout England and Wales. Moreover, this suggestion is in accord with the opinions of some observers who hold that a considerable number of the infectious diseases are to a certain extent insect borne. Typhus has been definitely proved to be spread in this manner.

Another remarkable feature of the report with respect to scarlet fever is that while the scarlet fever rate to the thousand persons was 2.23 for England during 1919, it was 60.98 for the country district of King's Lynn in Norfolk and 20.36 for the town of King's Lynn. It is true that these districts have a small population, which detracts greatly from their statistical value, yet the disproportion of the figures, to the rest of England, is so large that it would seem that Dr. Hamer's suggestion might be put to a practical test either in King's Lynn or in any other place where an unusual rate is found. It would seem after all that John Wesley's saying that "Cleanliness is next to godliness" is very near the truth and one to be highly commended as a health axiom. It has been denied that there is any inherent sanitary virtue in cleanliness and that after all it is but more or less an esthetic luxury. However, where dirt is there vermin flourish, and if vermin are carriers of disease, as they have been proved to be in the case of plague and typhus, and as they may be and probably are in scarlet fever and other infectious diseases, then the sanitary motto should be, let cleanliness and especially personal cleanliness prevail.

HEREDITARY TRANSMISSION OF SYPHILIS.

George Vella was the first to conceive the idea of the hereditary transmission of syphilis in 1508. After him came Jacob de Béthencourt in 1526, then Frascator, Massa, Feruel and Fallopius in the sixteenth century and Sylvaticus, in 1601. All these observers mention the hereditary transmission of the *mal français*, but they only seem to have encountered cases in which the manifestations of the infection appeared shortly after birth. Uçay, in 1699, first suspected that congenital syphilis might occur for the first time in late childhood or even in adolescence and he does not hesitate to say that "it

is from syphilis that so many hereditary diseases are derived, such as scrofulous tumors, old (chronic) ulcers, gouts and rheumatisms as well as the whites in women." Later writers on syphilis soon went astray in the matter of congenital syphilis, so that in 1736, the learned Astruc, although not admitting the transmission of syphilis by heredity in the strict sense of the meaning, believed that several very different affections, such as rickets or tuberculosis, were derived from what he termed degenerated syphilis.

Sanchez, Fabre, I. L. Petit, Rosen von Rosenstein and other writers of the eighteenth century went still further and attributed all sorts of disease—even alopecia areata—to hereditary syphilis. Toward the end of this century congenital lues dominated both in surgical and medical pathology with the exception of traumatic surgical affections. In these circumstances a reaction was bound to occur, so that Hunter refused to admit the transformations of hereditary syphilis, but he was wrong when he denied the possibility of the transmission of the infection from parent to offspring. Bell, in 1793, maintained that this transmission did exist and he even added that it might remain latent for some years. Then in 1828, Lagneau gave an excellent description of congenital syphilis, while Cullevier and Ration, in 1836, regarded the late manifestations as due to scrofula. Baumes, of Lyons, maintained in 1840 that congenital syphilis manifested itself, "sometimes while the child is in the uterus of the mother, at others at the time of birth, of a few months, a year, or several years after."

Thirteen years later, Ricord upheld his doctrine of tardy heredity before the Academy of Medicine of Paris, and in 1862 illustrious syphilologists declared that "late hereditary manifestations, not preceded by early accidents, must be regarded as an acquired fact," and since that time all writers on the subject have described two forms of hereditary syphilis; an early form with manifestations at birth or in early childhood and a late form arising in late childhood, at puberty or even later. Little attention has been given to the nervous manifestations of hereditary syphilis, although in 1712, Hoffmann said that he had cured a nervous affection by mercury in a young girl nine years old "of illustrious birth and whose father had been infected with a pox as thoroughly as one could be." At about the same epoch Beckers, Joseph Pleuck (1779) and Rosen von Rosenstein mention similar cases, while in 1783 Carrère attributed certain types of paralysis, epilepsy and apoplexy to hereditary syphilis. It was, however, only in the second half of the last century that hereditary cerebral syphilis commenced to be seri-

ously studied and although some well observed cases were reported before 1868, this year is memorable from the fact that Hughlings Jackson's paper appeared, *Cases of Diseases of the Nervous System in Patients Subjects of Inherited Syphilis*, which marked the beginning of our present knowledge of syphilis of the nervous system in subjects with hereditary syphilis.

PHYSICIAN-AUTHORS—DR. JOHN ARBUTHNOT.

There are many authoritative students of letters who contend that the clearest and most virile mind of all the wits of Queen Anne's reign was that of Dr. John Arbuthnot. To attribute to a man a brilliancy and depth of learning beyond that of Swift, Pope, Addison, Congreve, Gay, Atterbury and Parnell is indeed a tribute. Thackeray admired Arbuthnot above all his contemporaries and Samuel Johnson said: "I think Arbuthnot the first man among them." For that matter, the contemporaries themselves conceded his intellectual superiority and gracefully acknowledged many a debt to him. Why, then, is he not better known at present? Why is he now almost totally unknown and his writings practically unread? There are two main reasons. First, he has not survived in general literature because of the ephemeral nature of the topics he chose to write about. To appreciate his writings it is necessary to have a fairly complete knowledge of the period in which he dwelt. Second, Arbuthnot preferred to be a man of medicine. He had a complete lack of literary ambition and was contented to assist his contemporaries toward literary fame rather than to compete with them. He was lavish in his assistance of Pope, Swift and Gay. They were his intimate friends and got ideas and inspiration directly from him. Others got ideas and inspiration from him through his writings. Thus Dr. Arbuthnot may be said to owe his fame today to what he did not write rather than to what he wrote.

There are two satires by which Dr. Arbuthnot is chiefly remembered today. These are his famous *History of John Bull* and *The Memoirs of the Extraordinary Life, Works, and Discourses of Martinus Scriblerus*. The first of these, written in 1712, follows the structure of Swift's *Tale of a Tub* and is fully its equal in merit. It was an ingenuous and lively attack on the war policy of the Whigs and it achieved results. As an allegory of statecraft it remains without a rival and was the model of all political satires in England for a century or more after its appearance. But it was a satire of passing men and events and not built for lasting popularity. The most

enduring part of it has been its title. The appellation *John Bull* was originated by Dr. Arbuthnot and it has clung to the British nation ever since. So, too, has his description of John Bull. The John Bull of the cartoonists today is John Bull as Dr. Arbuthnot described him.

The *Scriblerus Memoirs* ranks as one of the finest pieces of sarcastic humor in the language. It was from this work that Sterne appropriated the bulk of his material for the earlier chapters of *Tristram Shandy* and the same source gave Swift his inspiration for *Gulliver's Travels* and Pope the inspiration for his *Dunciad*. "If the world had but a dozen Arbuthnots in it," said Swift, "I would burn my *Travels*." Pope in his *Epistle to Dr. Arbuthnot*, which forms the prologue to his satires, pays further generous tribute to his learned friend. The *Scriblerus Memoirs* were first printed in some of Pope's works. They were the outgrowth of the Scriblerus club which Arbuthnot, Swift, Pope and others of the Queen Anne galaxy organized in London. The so-called memoirs were to have consisted of several books satirizing the abuses of learning, and several members of the club were to have collaborated in the writing of them. Only the first book, by Arbuthnot, was completed.

Other writings of Arbuthnot included *Virgilius Restauratus*, in which he gave us Virgil corrected and improved in a playful vein; *The Art of Political Lying*, which would seem not to have permanently corrected this evil; a monograph entitled *An Argument for Divine Providence*, essays *On the Usefulness of Mathematical Learning*, and a considerable number of other essays on subjects of current interest.

Dr. Arbuthnot was born at Arbuthnot, Kincardineshire, Scotland, in 1667. He attended the University College at Oxford from 1694 to 1696 and took his medical degree later at St. Andrew's University, Aberdeen. He established himself in medical practice in London, but patients were few and far between and he supplemented his income by teaching mathematics. He found time, also, to compile a comparative table of Greek, Roman and Jewish measures, to translate from the Dutch *The Laws of Chance, or a Method of Calculating the Hazards of the Game*, and to do a little writing. His fame as a wit and man of learning was growing but his medical practice was not. Then came a stroke of good fortune. Prince George of Denmark, husband of Queen Anne, fell ill at Epsom and Dr. Arbuthnot happened to be there at the time. No other physician being immediately accessible, he was called in, and became the prince's physician during the rest of his life. Shortly thereafter, in 1705, he also became physician extraordinary to the queen. His

medical reputation was established and distinguished patients flocked to him by the dozens. In 1723 he became one of the censors of the Royal College of Physicians and in 1727 he delivered the Harveian oration, the supreme medical honor of the day.

Pope said of Dr. Arbuthnot that "He was as good a doctor as any man for one that is ill and a better doctor for one that is well." His principal medical writings were *An Essay Concerning the Nature of Ailments*, in which he argued, among other things, that all that is done by medicine might be equally well done by diet, and *An Essay Concerning the Effect of Air on Human Bodies*. Sir Benjamin Richardson called this second work "one of the most remarkable books in the literature of medicine" and pointed out that Arbuthnot was far in advance of his age in medical science and made some remarkable discoveries. Dr. Arbuthnot died in 1735 at the age of sixty-eight.

PROGRESS IN PSYCHIATRY.

An unusually fascinating records of events is presented in Professor Kraepelin's [Prof. Emil Kraepelin: *Hundert Jahre Psychiatrie, Ein Beitrag zur Geschichte menschlicher Gesitung, Arbeiten aus der Deutschen Forschungsanstalt für Psychiatrie in München*, Vol. I, Berlin, Julius Springer, 1920.] paper, which introduces the recently published first report of the new German institute for research in psychiatry. The slow development of scientific interest in this important field is told in such manner that one is compelled to acknowledge the magic of evolutionary growth which not even the thick prejudices of selfdefending ignorance are able to stem. Progress forces its way, however it is temporarily halted by such barriers, however its force is partially dissipated in half fruitless experiments at understanding mental disease. It lies in the essence of human nature that it casts strong defenses about itself in its timidity toward what is still unknown, that it hinders just that work into which it is drawn by its own instincts.

So it has come about that in the realm which belongs to psychiatry, that of mental disease, timidity and ignorance supporting one another have made the road into intelligently humane treatment of the insane a long, hard one. For understanding is in its very nature fellow feeling, and therefore to admit that one understands mental disease implies participation in experience with the sick. The mind is afraid of such acknowledgment and strongly on its guard against it. Thus, feeling at least maintains an ignorance of mental disease as long as is possible and, as must be admitted, long after science has professed enlightenment of these darksome matters.

It is not strange that even a few decades ago the mentally diseased were shoved aside from a calm businesslike approach to their problems and were relegated to the forcible confinement of cells and chains; or their agonies of mind and absurdities of behavior were the work of the devil or of evil propensities on their own part which must be ejected by the severest discipline. It is difficult even today to acknowledge that a neighbor's differing conduct or his opinion that varies from an established code can deserve a considerate approach which might at least lead to understanding and perhaps acceptance. One can still preserve one's own accustomed attitude so much more comfortably by putting him in chains or submitting him to exorcising tortures. For these in themselves set the stamp of disapproval and therefore release from further responsible effort.

All these considerations, not intellectually but rather intuitively adhered to, hindered but could not permanently retard the gradual introduction into psychiatry of real investigation into the state of the mentally sick and the possibility of elements of humanity still residing beneath the sufferers' apparent strangeness. So with experiment in many directions, with an attitude of sympathetic approach of one sort and another a way was gradually made into the darkness.

The granting of freedom of body to those once shackled was at the same time justified by the slow discovery that there was a certain freedom and elasticity of the mind in which access to the sick person could be attained. Possibility of healing still remained. The varied attempts made under such awakening human interest foreshadowed the varieties of approach which today maintain an even surer hold upon medical thought. They arose then out of the principle of unity which lay in the nature of mind and body with their close interrelationship, they ground themselves today even more deeply in such foundation. They tend in it to a simpler basis of understanding. Yet from this they again branch into ever widening territories in which mental disease must be variously studied.

To such broadening end Kraepelin's review of psychiatry leads. To fruitful attack upon the problems of mental disease in these various spheres he points with hopeful inspiration. Looking backward or looking forward, his words are such as to enlist the reader's interest. It is to be regretted that he has not disclosed more deeply the fruitful psychical field which can lay claim to no less importance than the anatomical and in which he might have said much more of the profounder implication of psychic factors in mental disturbances.

THE TORONTO CANCER CURE.

When the medical profession has before it many well authenticated cases of epitheliomatous cancers (of two or three months' rapid growth), cured by radium in six weeks or two months, then they begin to wonder why Dr. T. J. Glover, Toronto, withholds even a progress report on his serum treatment of cancer, which, during the past two or three months, has received such wide publicity in the lay press of both Canada and the United States. Many hundred cases have been treated in St. Michael's Hospital, Toronto, but within the past month, a millionaire's mansion has been purchased for Dr. Glover, and his patients are said to run at the present time into the hundreds. The newspaper press has been supplying the profession of some details of the work but so far not a single case of cure has been reported.

The medical press in Toronto are now calling the attention of Dr. Glover to this very unusual, if not unethical, way of bringing a cure for cancer before the medical profession; and some nasty remarks have been made even in the newspaper press about the intention of Dr. Glover keeping his cure secret for the benefit of his own personal gain. So far as the profession in Toronto is concerned, they would like to have some pronouncement from Dr. Glover either in the scientific press of Canada, England, or the United States; or perhaps better before the local medical body—the Academy of Medicine. Cancer is such a terrible disease, so hopeless of cure, that the profession would be very glad and proud of the facts if a real cure emanated from Toronto; but in the plainest English they hope that there is now sufficient data available to warrant Dr. Glover giving it to the profession in the regular way for benefit of mankind at large.

OVERWORK A STIMULANT.

The up to date factory physician and inspector are wide awake in their researches into sleep and fatigue. If employees could be massed together as to needful rest all would be easy, but the constitution and endurance of every man vary. It is noted by Spaeth (*Industrial Management*, 1920) that with most, normal fatigue is usually relieved by sleep and food; in some, it quickly goes on to cumulative fatigue, the precursor of nervous breakdown. Curiously, recent observations have shown that production actually increases with fatigue within certain limits; feverish haste and a dislike of not finishing up are not infrequent even when the work is not congenial.

ORANGEADE.

"Made from fresh oranges," so the vendor at the stall says; but the Bureau of Chemistry at Washington, D. C., otherwise labels it. The drink is usually made from sweetened, artificially, carbonated water colored with a dye to imitate orange juice and flavored with a little oil from orange peel. While not containing ingredients injurious to the health of adults, they are imitations and the young do not get the medicinal or food value of fruit juice. Such drinks do not come under the Food and Drugs Act.

News Items.

French Speaking Physicians Meet.—French speaking physicians of North America held their sixth congress September 9th to 11th at Quebec, under the presidency of Dr. Arthur Rousseau.

Southern Medical Association.—The Southern Medical Association will meet November 15th to 18th in Louisville, Ky., under the presidency of Dr. E. H. Cary, of Dallas, Tex.

Louisiana Lepers' Home Sold.—The Louisiana leprosarium at Carrville, La., has been sold to the Federal Government for use as a national leprosarium. The institution and the lepers who are inmates will be taken over by the U. S. Public Health Service.

Infantile Paralysis.—Figures given out by the Health Department indicate that there have been sixty-five cases in this city since January 1st and thirty-eight in the last month. Sixteen cases were reported in one week in the latter part of September. There have been six deaths in two weeks.

Southwestern Medical Association.—The Southwestern Medical Association, which comprises the states of Missouri, Kansas, Oklahoma, Arkansas and Texas, will hold its fifteenth annual meeting November 22nd to 24th at Wichita, Kan., under the presidency of Dr. E. E. Day, of Arkansas City, Kans.

Consultation Clinics in Massachusetts.—The Massachusetts State Department of Public Health has announced its plan of holding a series of consultation clinics in early pulmonary tuberculosis, to be conducted by the medical staff of the state sanatoria. Patients will be referred to the clinics by the family physician.

Hospital Fund Drive.—The United Hospital Fund, comprising forty-six Manhattan and eight Brooklyn nonmunicipal hospitals, will endeavor to raise a fund of \$1,500,000 beginning November 15th. This sum will represent approximately half the expense incurred in giving free treatment to those who are unable to pay.

Chair in Bronchoscopy and Esophagoscopy.—The Graduate School of Medicine of the University of Pennsylvania has established the first medical chair in bronchoscopy and esophagoscopy, the incumbent being Dr. Chevalier Jackson, of Philadelphia. Dr. Jackson will also continue his work at Jefferson Medical College, where he is professor of laryngology.

Attend Medical Congress.—A number of medical men sailed on September 30th on the *Mauretania* to attend the International Congress on the Classification of the Causes of Death, in Paris. The congress has been called by the French Government and will last ten days. Dr. Haven Emerson, former health commissioner, representing the Public Health Association; Dr. F. J. Monaghan, assistant health commissioner, and Dr. W. H. Guilfoyle, director of the Bureau of Vital Statistics of the Health Department, who represent the City of the New York; Dr. Otto Eichel of the Bureau of Vital Statistics of the State Department of Health, Dr. W. H. Davis of the United States Bureau of Census in Washington were passengers.

Miners' Hospital.—A \$200,000 hospital for the exclusive use of coal miners is to be erected in Charleston, W. Va., by District No. 17, United Mine Workers of America.

Quarantine Mexican Tourists.—Because of the prevalence of yellow fever in the seacoast cities of Mexico, the U. S. Public Health Service has placed quarantine restrictions against all travelers from those ports.

Sir Arthur Newsholme Returns.—Sir Arthur Newsholme, resident lecturer on Public Health Administration at the School of Hygiene and Public Health, Johns Hopkins University, has returned to Baltimore after having spent the summer at his home in England.

The Harvey Lectures.—Dr. Jacques Loeb, of the Rockefeller Institute for Medical Research, will deliver the first of the Harvey Society Lectures at the New York Academy of Medicine, Saturday evening, October 16, 1920. His subject will be The Proteins and Colloidal Chemistry.

Tuberculous Soldiers Ordered from Saranac Lake.—Tuberculous ex-service men who are being cared for by the government at the Home Sanatorium, Saranac Lake, N. Y., have been ordered transferred to New Haven and other government hospitals by October 15th.

Women in Virginia Medical Faculty.—The Medical College of Virginia, in Richmond, which last year opened its doors for the first time to women students, now has its first woman professor, Dr. Margaret Morris Hoskins, associate professor of anatomy. Dr. Hoskins was formerly at the University of Minnesota.

Vienna Doctors Strike.—A press dispatch from Vienna states that about four thousand doctors who have been treating patients under the auspices of sick benefit associations have gone on strike, and have refused to make visits except for the regular fees of their private practice.

Intoxication Increasing.—The number of arrests for intoxication in New York city is increasing, according to a statement issued by Chief City Magistrate William McAdoo. The figures for the first six months of 1920, from January to April, give the total number for the Greater City as 571. During April, May and June these figures rose to 1,396, approximating those of the first part of 1919. Violence which follows intoxication shows that the liquor in many instances must be of high alcoholic strength.

Change of Address.—Dr. Wolff Freudenthal announces the removal of his office from 59 East Seventy-fifth Street to 24 West Eighty-eighth Street, New York.

Dr. Maurice Packard announces his removal to 17 West Seventieth Street, New York.

Dr. Byron C. Clark announces the removal of his office to 163 West Ninety-second Street, New York.

Dr. Robert Abrahams has removed his office to 260 West Seventy-second Street, New York.

Dr. Abr. L. Wolbarst announces his removal from 113 East Nineteenth Street, to 792 Lexington Avenue, New York.

Dr. Jacob Rosenbloom announces his removal to 120 West Seventieth Street, New York.

Baltimore Charity Hospitals Raise Rates.—Baltimore hospitals which contract for the care of city patients have notified the municipality that they will not renew the contracts at the old rate of one dollar a day. They ask three dollars a day for each patient cared for in the future. The hospitals include the Maryland General, Franklin Square and St. Agnes.

State Hospital for Ex-Service Men—An appropriation of \$3,000,000 has been made by the New York State Legislature for the establishment of a state hospital for discharged soldiers, sailors, and marines suffering from mental diseases. The hospital will be built in the Borough of Queens, on land acquired for the Long Island State Hospital, and will have a capacity of 1,000 beds.

Ambulance Drivers Lacking.—Bellevue Hospital is experiencing a shortage of ambulance drivers, and for the first time since the establishment of Bellevue Hospital in 1736 the working hours of ambulance drivers have had to be changed. It was announced that the drivers will work twenty-four hours on and twenty-four hours off, instead of a six day week with the seventh day off as heretofore.

Hospital Bequests.—Under the will of Max J. Breitenbach, of New York, the following bequests are made to charitable and educational institutions: New York College of Pharmacy, \$25,000; Sanitarium for Hebrew Children of the City of New York, \$5,000; Montefiore Home, \$5,000; Beth Israel Hospital, \$5,000; Lebanon Hospital, \$5,000; Jewish Maternity Hospital, \$5,000; Crippled Children's East Side Free School, \$5,000; Mount Sinai Hospital, \$3,000; Hospital at Albany, Ga., \$1,000.

The will of Jacob H. Schiff, which has recently been made public, contains many bequests to charitable institutions. The Montefiore Home and Hospital for Chronic Diseases, of which the testator was for many years president, receives \$300,000. Other bequests were: Solomon and Betty Loeb Memorial Home for Convalescents, \$25,000; New York Association for the Blind, \$10,000; Babies Hospital in the City of New York, \$5,000; Tuberculosis Preventorium for Children at Farmingdale, N. J., \$5,000.

A gift of \$50,000 has been made to the Ware Visiting Nurse and Hospital Association, Ware, Mass., by the late Lewis N. H. Gilbert, of that place.

Local Medical Societies.—The following local medical societies will meet during the coming week:

MONDAY, October 11th.—Society of Medical Jurisprudence, New York Ophthalmological Society, Yorkville Medical Society, Association of Alumni of St. Mary's Hospital (Brooklyn), Williamsburg Medical Society.

TUESDAY, October 12th.—New York Academy of Medicine (Section in Neurology and Psychiatry), Manhattan Dermatological Society, New York Obstetrical Society, Clinical Society of the Hospital and Dispensary for Deformities and Joint Diseases.

WEDNESDAY, October 13th.—Medical Society of the Borough of the Bronx, New York Pathological Society, New York Surgical Society, Alumni Association of Norwegian Hospital, Brooklyn Medical Association.

THURSDAY, October 14th.—New York Academy of Medicine (Section in Pediatrics), West End Clinical Society, Brooklyn Pathological Society.

FRIDAY, October 15th.—New York Academy of Medicine (Section in Orthopedic Surgery), Clinical Society of the New York Postgraduate Medical School and Hospital, New York Microscopical Society, Brooklyn Medical Society.

Health Department Budget.—Dr. Royal S. Copeland, health commissioner, has asked for an appropriation of \$8,821,027.23 to run the New York City Department of Health for 1921, against \$4,758,951 for 1920. Of this amount \$7,551,978 is to run the department and the difference is for new buildings. One of the new activities for which the Commissioner is asking an annual salary list of \$11,600 is the establishment of a Bureau of Public Health Intelligence. Dr. Copeland said that for two years the department had been asking for a new official to watch the trend of disease in this city and throughout the world, in order to apply advance information for the safeguarding of New York against invasion by disease. The director of this bureau is to receive \$5,000 a year.

Dr. Copeland has asked for an allowance that would enable him to engage thirty inspectors of food at \$1,769 each, sixty-eight nurses for maternity work, nine dentists at \$1,244 each, nine nurses at \$1,800 each, and 18 dental hygienists at \$960 each.

It is the Commissioner's desire to increase facilities for making the Schick test for diphtheria. He estimated the needs of the department for this work as six medical inspectors at \$1,464 each a year, six nurses at \$1,800 each, and five laboratory helpers at \$840 each. He asked also for \$2,550 for a bacteriological diagnostician and a sum to allow for increasing the force of laboratory assistants and helpers. The department is asking that supervising nurses receive a salary of \$1,980 a year and field nurses \$1,800 a year. To do this \$46,217 will be required.

Died.

BOSHER.—In Richmond, Va., on Sunday, September 12th, Dr. Lewis Crenshaw Boshier, aged sixty years.

BURCH.—In Long Lake, N. Y., on Wednesday, September 22nd, Dr. Elmer D. Burch, aged fifty-three years.

COLE.—In New York, N. Y., on Saturday, September 25th, Dr. John D. Cole, aged sixty-three years.

HARRISON.—In Roanoke, Va., on Wednesday, September 1st, Dr. Henry William Harrison, aged seventy-one years.

HILL.—In Nanticoke, Pa., on Sunday, September 26th, Dr. Jacob Franklin Hill, aged sixty-four years.

JAMES.—In New York, N. Y., on Wednesday, September 29th, Dr. Howard James, aged fifty-five years.

JOHNSON.—In Los Angeles, Cal., on Friday, September 17th, Dr. Walter Sydney Johnson, aged forty-nine years.

KEAN.—In Manchester, N. H., on Thursday, September 23rd, Dr. M. E. Kean.

KOONS.—In Waynesboro, Pa., on Wednesday, September 29th, Dr. John H. Koons, aged sixty-six years.

MORGAN.—In Rolling Bay, Wash., on Monday, September 20th, Dr. William P. Morgan, aged seventy-four years.

ROBERTS.—In New York, N. Y., on Monday, September 27th, Dr. Charles Forrester Roberts, aged seventy-eight years.

STERLING.—In Philadelphia, Pa., on Friday, September 24th, Dr. Joseph Marshall Sterling, aged thirty-one years.

THOMAS.—In Wilmington, N. C., on Sunday, September 5th, Dr. George Gillette Thomas, aged seventy-seven years.

UPSON.—In Bristol, Conn., on Tuesday, September 21st, Dr. Charles Ransom Upson, aged sixty-eight years.

WOOLF.—In New York, N. Y., on Sunday, September 26th, Dr. Edgar Morton Woolf, aged thirty-two years.

Book Reviews

NEW VIEWS ON GOITRE.

Exophthalmic Goitre and Its Nonsurgical Treatment. By ISRAEL BRAM, M. D., Instructor in Clinical Medicine, Jefferson Medical College, Philadelphia, etc. St. Louis: C. V. Mosby Company, 1920. Pp. ix-438.

Readers of the *NEW YORK MEDICAL JOURNAL* will welcome Dr. Bram's book on the nonsurgical treatment of exophthalmic goitre. Much that is in the book has appeared in the *JOURNAL*. As the book stands today it is the most thorough exposition of Graves's disease to be found. When the risk attending surgical removal of the thyroid is considered and when we realize the splendid results that have been obtained by nonsurgical treatment, it is absolutely necessary to study the disease from the nonsurgical viewpoint. It is not to be thought that nonsurgical means only medicinal. The nonsurgical treatment embraces many methods of treatment, local, general and psychotherapeutic, and Bram has gone into the subject thoroughly, attacking it from every angle. He first studied the patient and the patient's life in an endeavor to trace the real etiology of the disease; he is not misled by the surface findings nor does he accept the apparent causative factors of the disease.

Following this, he endeavors to ascertain the value of every form of treatment, giving due credit to each one. He shows that the manifestations of goitre may be symptoms having many underlying causes. They may be the defense reaction of one leading a lonely home life; they may be fear reactions caused by the outcropping of the latent unknown content of the patient's unconscious. He shows the importance of the endocrine chain and how easily the equilibrium of the chain is upset. This knowledge is made use of in a diagnostic way when endocrine diagnostic tests, like the pituitary test, are utilized. It is also of primary importance in the treatment of the disease. While the study of practical endocrinology is in its infancy, we are now beginning to use much of the knowledge that has been acquired in the laboratory, linking it up with our clinical finding, and applying these findings in a therapeutic way. The results have been most encouraging and in many cases startling.

The use of the x ray has also found favor among many and in the hands of skilled operators has proved far more efficacious than the ordinary surgical procedures. Radium also has frequently given excellent results. Bram has given us a host of remedial measures and in many cases one remedy may prove to be excellent where another may fail. Some observers maintain that they have had a number of positive cures with every one of the therapeutic methods they have employed as their favorite one. Yet it cannot be said in looking over the entire list that any one of these can be called a specific for the cure of thyroid disease. There must be something more behind all this. The answer is given when we search for the etiology of the disease. Bram helps us materially when he stresses the underlying psychic factors and shows how they are universally responsible for setting the responsive mechanism of a susceptible patient into operation and thereby

causing the chain of symptoms, either separately or to the completion of the entire clinical picture known as Graves's disease or true exophthalmic goitre. Therefore, it is safe to assume that much of the good that has come from the many measures mentioned by Bram has come through the rapport established between the patient and the physician; a condition technically known as transference.

The patient, feeling inadequate within himself, a martyr, unburdens himself to the physician. In many instances this alone will tend to improve the patient's condition. The more thoroughly this rapport is established, the more interest the physician takes in the intimate life of the patient, the more will the benefit of this procedure be found. Naturally the patient must reveal, as far as he is able, the things that trouble him. Frequently it is impossible for the patient to know what the underlying difficulty is, for it will be buried deeply in his unconscious. Bram shows that it is most important to ascertain the patient's habits, tendencies, petty obsessions, and vices. In speaking of this Bram quotes Weir Mitchell, who said that "The cases of breakdown and nervous disaster, and the consequent emotional disturbances and their bitter fruit are oftener to be sought in the remote past. He may dislike the quest but he cannot avoid it. * * * The moral world of the sick bed explains in a measure some of the things that are strange in daily life, and the man who does not know sick women does not know women." Confidence must be secured. Once this is done rapid strides will be made. Sympathy must be extended and the patient must know that the physician is interested in the welfare of the patient. Then the patient must be reeducated and be taught to stand on his own feet, take an independent place in the world, and be made selfreliant.

Frequently the patient's friends and relatives, those of a talkative trend, have a bad influence upon him. They may in some cases be the cause of the patient's condition. All that must be ascertained and the objectionable surroundings removed, e. g., the talkative friends. The patient's general hygiene must not be neglected. There must be regularity of bathing, sleep, rest, exercise, feeding; in fact, the general condition of the patient must receive careful attention. One of the important issues emphasized by Bram is the sexual life of the patient. He shows how powerful a factor this may become under certain conditions. Sexual instruction must be given, after the sexual cravings and sex life of the patient have been determined.

This leads us to the social environment of the patient. In treating a patient we seldom inquire into this part of their lives. We know, and Bram realizes it, that the patient's household may be an inferno seething with suppressed antagonisms and hatreds. A patient's condition cannot readily improve under these circumstances and all the medication and surgical intervention known to medical science will not get at the bottom of the difficulty. The only advantage of a radical surgical operation is secured by the removal of the patient, for the

time being, from the unfavorable surroundings to the hospital.

Bram's book is replete with just such useful information. We realize that a busy surgeon, or general practitioner, for that matter, will not, as a rule, go into all of the details of the patient's life as he should in handling a delicate situation. He will be more likely to attempt a more perfect technic for the operation. However, we are coming more and more to realize that the high psychic levels of the patient are important—most important. Nevertheless, it is essential that some basis of therapy, similar to that mapped out by Bram, should be attempted before surgical measures are used. In most instances surgery will not be required. Even the surgeon would do wisely to ascertain what can be done outside his own field in the treatment of Graves's disease. In consideration of the importance of the subject and the careful handling it has received in this book it may be considered as one of the most important additions to medical literature of the present day.

ALTITUDE AND HEALTH.

Altitude and Health. (The Chadwick Lectures.) By F. F. ROGET, a Privat-Docent Professor in the University of Geneva. New York: E. P. Dutton & Co. Pp. xii-186.

The heights by great men reached and kept
Were not attained by sudden flight,
But they, while their companions slept,
Were toiling upwards in the night.

And while we were ignorantly huddled in the plains, and maligning cold air, Professor Roget and dozens like him, were frantically waving to us from the heights to follow on. But we shut our windows tighter and feebly shouted that we had a cold on our chest. "Nonsense," called out the mountaineers, "it's on your mind." But we created and filled a few more cemeteries before learning that they were right. We have learned that the immune countries are the coldest. That phthisis is accelerated where the average shade temperature is very high, and reaches its maximum of frequency in those regions of the temperate European zone which are only moderately cold, whether low lying or not. A few ventured up and were improved, but there is probably a precise altitude which is the best individually, and to that side deep attention is being given. Men go up there worn with toil or illness. "They have spent their reserve of nutrition and have not had time to replenish their store of warmth, so they must be reconstituted by a larger and wiser choice of food. Another evil arose from mountain stations being advertised as winter playgrounds. It would have been well but the visitors brought civilization with them. Out of doors all day—splendid—but the evenings were spent in crowded hotels and closed bedrooms. All the wicked germs who had to come with them expecting speedy death, gambolled about boldly and thrived. Overcrowding is as unsanitary in the Swiss Alps as in cities. But those invalids who live there, who have learned to avoid overexertion with consequent reaction and have got the body to fulfill of its own accord the conditions which will procure a regular output of warmth, cannot now return to the lowlands without a return of their illness.

Prefaced by a kindly and patient explanation of all that a change to high altitude means (and the author speaks after thirty-five years' experience) he goes more fully into the thermic, electric, barometric and hygrometric conditions, also pointing out that it is necessary to distinguish enrichment of blood at altitudes (say, not exceeding 10,000 feet) and impoverishment, which certainly begins for most at 8,000, particularly within the tropics. To distinguish between these two stages is the office of the new science, hematology, in which Dr. H. C. Lombard and Dr. William Marcet have done splendid work.

The chapter on Air at Altitudes is easy and pleasant reading and gives the balloon experiments of Professor J. Quale of Zurich with mountain sickness and blood and the latest British experiments by Barcroft, Roberts, Mathison and Ryffel. The monks in the Great St. Bernard Pass and the community at Avers are well described. The mortality statistics concerning them enlist the attention in an unusual way. The claims of the seacoast are admitted, but highest honor is given to the sun as doctor and friend. Some of the stodgy volumes on the question of altitude and health show how difficult it is to fit pretty garments of speech on angular facts, or to write persuasively so that those damaged in health may joyfully pack their suitcases and climb to health, but we can imagine many wheezing, coughing, holloweyed, one-foot-in-the-grave persons taking that foot out again and, limping but rejoicing, seeking the pure air of the mountains.

A LABOR VERSUS CAPITAL PLAY.

Touch and Go. A Play in Three Acts. Plays for a People's Theatre. By DAVID H. LAWRENCE. New York: Thomas Seltzer, 1920. pp. v-103.

Mr. D. H. Lawrence, whose field has heretofore been the analysis of more personal passions, has turned his eye upon the industrial situation and produced a labor capital play, a play with a preface. As is usual in such instances, the preface is more illuminating than the play. In the preface Mr. Lawrence tells what he thinks about a great many subjects, including a People's Theatre. A People's Theatre he conceives as a place where will be produced plays about people—"not noses on two legs, not burly pairs of gaiters, stuffed and voluble, not white meringues of chastity, not incarnations of co-responsence"—in contradistinction to the *Chu Chin Chow* sort of thing.

Unfortunately *Touch and Go* is not a play about people. It is a tedious and wordy affair, utterly lacking in direction or in high moments. The theme is a strike in the colliery of Barlow and Walsall and young Gerald Barlow's refusal to have anything to do with what he regards as a mess. In the mob scene at the end Gerald tells the men that he wants a new way of life, that he doesn't care about money, but that he is not going to be bullied. And a ribald voice from the mob, with one of the few touches of conviction in the play, answers, "No, because you've got everything."

If the characters are to be taken as at all representative of their respective classes, Mr. Lawrence regards labor as inexpressibly stupid and capital as jaded but stubborn. He also regards them as natu-

ral enemies. "The two dogs are making the bone a pretext for a fight with each other. . . . Labor not only wants his debt. He wants his pound of flesh. . . . What's the solution? There is no solution. But still there is a choice. There's a choice between a mess and a tragedy." Possibly the workers will not be as concerned as Mr. Lawrence in seeing that they are tragical instead of messy and in going through the conflict beautifully. There are affairs of more importance. Mr. Lawrence in this play writes like a minor poet who has strayed from his daisy field.

A PSYCHOANALYTICAL SHERLOCK HOLMES.

The Ivory Disc. By PERCY JAMES BREBNER. New York: Duffield & Co., 1920. Pp. 254.

An uncanny kind of doctor is taking the place of the ones created by Barrie, Wendell Holmes and earlier writers. He is a psychoanalytical Sherlock Holmes with a touch of the Eastern mystic, yet sufficiently human to yield to the modern idea that love is to take, no matter how many husbands or children the lady already possesses. He has a laboratory, always locked, and is experimenting with some new poison which will kill the toughest villain in five minutes. Or a sudden death has occurred. "Heart disease," says the jury, but the doctor's steely blue eye has a peculiar glint of suspicion in it. He has the body exhumed and triumphantly exposes the villainy of a murderer.

Dr. Bruce Oliver manages to carry on his detective work and woo the wife of a polished Indian professor at the same time. Now this professor sends his pretty young English wife around with a ring containing subtle poison which she unconsciously injects during a handshake, and it naturally makes him angry to see his wife growing to lose her fear of him and his hypnotic powers lessening. Meanwhile Dr. Oliver "felt that she was his, not through overmastering passion, but by right of love. He had said no word of love to her until love was with them suddenly, not to be denied, not to be considered a crime." His only hope lies in exposing the professor, but this man is very wily and glosses evil intentions with a suave manner. His evil intention of adding the doctor to his poisoned victims is frustrated by the ivory disc, a talisman given him by Estelle, the bad professor's wife, whom he finally persuades to leave her husband and live in a lonely cottage with a trained nurse until a divorce or annulment of Indian marriage is obtained. While there she greatly desires her dog, and Dr. Oliver will fetch it for her. Then we have a mysterious house right in the heart of London, dim lights, soft footed servants, a sudden surprise in the professor's study and Oliver is swiftly strapped to a chair until his enemy shall choose to touch him with the fatal ring. But the Indian servants discover the talisman on his neck and superstition induces them, when bidden to leave the room, to loose the big dog, who hates the professor, for his protection. Brutal thrashings, since Estelle's departure, have made the animal vindictive. He scents out his master just as the hour has struck for the poisoning, then a deadly, horrible

fight takes place with Oliver utterly powerless to help. Finally the professor is killed, the dog also, because it rubs against the ring, and the doctor is free to wed Estelle.

The story will be enjoyed by those who revel in improbabilities. We do not meet any of these mysterious practitioners in New York; they have enough to do getting toxins out of their patients without putting any in. Of course, the women patients can invest the most plump, jovial and ordinary doctor with occult powers. Many owe their large practice to this blessed blindness of woman-kind, but if such stories as these flood in we shall have even women a little inclined to avoid friendly handshakes, hypnotizing glances, dimly lighted reception rooms and anything supposed to be oriental.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

TRUE LOVE. By ALLAN MONKHOUSE. New York: Henry Holt & Co., 1920. Pp. vi-373.

THE BROKEN LAUGH. By MEG VILLARS. New York: Robert M. McBride & Co., 1920. Pp. vii-343.

THE ELFIN ARTIST AND OTHER POEMS. By ALFRED NOYES. New York: Frederick A. Stokes Company, 1920. Pp. ix-187.

TOUCH AND GO. A Play in Three Acts. Plays for a People's Theater. By D. H. LAWRENCE. New York: Thomas Seltzer, 1920. Pp. v-103.

HEALTH AND SOCIAL PROGRESS. By RUDOLPH M. BINDER, Ph. D., Professor of Sociology, New York University. New York: Prentice-Hall, Inc., 1920. Pp. i-295.

ALL THINGS ARE POSSIBLE. By LEO SHESTOV. Authorized Translation by S. S. KOTELIANSKY. With a Foreword by D. H. LAWRENCE. New York: Robert M. McBride & Co., 1920. Pp. vii-244.

PROBLEMS OF POPULATION AND PARENTHOOD. Being the Second Report of and the chief evidence taken by the National Birthrate Commission, 1918-1920. New York: E. P. Dutton & Co., 1920. Pp. v-423.

MIND ENERGY. Lectures and Essays. By HENRI BERGSON, Member of the French Academy, Professor in the College de France. Translated by H. WILDON CARR, Hon. D. Litt., Professor in the University of London. New York: Henry Holt & Co., 1920. Pp. x-262.

LETTERS FROM THE KAISER TO THE CZAR. Copies From Government Archives in Petrograd Unpublished Before 1920. Private Letters From the Kaiser to the Czar Found in a Chest After the Czar's Execution and Now in Possession of the Soviet Government. Copied and Brought From Russia by ISAAC DON LEVINE. Illustrated. New York: Frederick A. Stokes Company. Pp. xxxv-264.

THE SHIBBOLETHS OF TUBERCULOSIS. By MARCUS PATERSON, M. D., Medical Superintendent, Metropolitan Asylums Board, Colindale Hospital; Late Medical Superintendent, Brompton Hospital Sanatorium, Frimley; Medical Director, King Edward VII Welsh National Memorial Association; Resident Medical Officer, Brompton Hospital, London. New York: E. P. Dutton & Co., 1920. Pp. xi-239.

OPERATIVE GYNECOLOGY. By HARRY STURGEON CROSSEN, M. D., F. A. C. S., Associate in Gynecology, Washington University Medical School, and Associate Gynecologist to the Barnes Hospital; Gynecologist to St. Luke's Hospital, St. Louis Maternity Hospital, and Bethesda Hospital. Second Edition. Illustrated. St. Louis: C. V. Mosby, 1920. Pp. v-717.

Miscellany from Home and Foreign Journals

Delayed Arsenical Poisoning Following the Administration of Salvarsan Preparations.—George S. Strathy, C. H. V. Smith, and Beverley Hannah (*Canadian Medical Association Journal*, April, 1920) report their observations in fifty-eight cases of delayed poisoning following administration of salvarsan and mercury. Forty-seven of these showed symptoms referable to the liver, jaundice, decreased digestive power, and liver atrophy. Eight were fatal and showed at autopsy marked atrophy of the liver. Atrophy of the liver may be marked in patients who ultimately recover. This condition can be diagnosed by the x rays. Dermatitis occurred in eight cases; five were severe with marked exfoliation. Peripheral neuritis was observed in two cases. Albuminuria was present in over fifty per cent. of the cases; edema was found in two. The onset of the symptoms seldom occurred until five weeks after the administration of salvarsan had ceased. The earliest symptoms of poisoning of the liver were bile in the urine, albuminuria, loss of appetite and jaundice. These symptoms should be looked for in all patients receiving salvarsan treatment, and on their appearance the administration of the remedy should cease. By x ray examination atrophy of the liver may be diagnosed at an early stage. Where evidence of liver damage is present, the diet should be reduced to a minimum. Dermatitis with atrophy of the liver occurred in one patient who received arsenic in the form of Fowler's solution, five minims three times a day for five months.

Specific Aortitis.—William D. Reed (*Boston Medical and Surgical Journal*, July 15 and 22, 1920) says that syphilitic disease of the aorta is one of the most common and most serious findings in all cases of acquired syphilis. The lesion is essentially mesoaortitis, and a manifestation of active syphilis; its conception as a parasymphilide being made untenable by the discovery in 1906 of the spirochete directly in the aortic lesion. The aortic process frequently extends to the aortic cusps, and Warthin has shown that relatively often there is an accompanying myocarditis of spirochetal origin. Aortic roughening, aortic regurgitation, dilatation or aneurysm of the aortic arch, and angina pectoris are common in syphilitic aortitis. Aortic or mitral stenosis is of exceptional occurrence in connection with specific aortitis. Nonsyphilitic forms of aortitis are rare. Many cases may be called latent, in that symptoms are absent; such cases are commonly undiagnosed until disclosed, perhaps, in a routine röntgen examination. There is no one point on which a diagnosis should be based, but only after a study of all the facts in a given case should a decision be rendered. Every case of cardiac disturbance of obscure origin, especially if the patient is a young adult, and if there are signs of involvement of the aortic valve, should promptly suggest the probability of syphilitic causation. A positive Wassermann reaction is of confirmatory value, but is frequently absent. Röntgen examination, though unreliable in early cases, gives

perhaps the most reliable findings. Specific aortitis evidences a tendency to progressive impairment of the heart and aorta and is of serious import. Treatment should be directed primarily toward killing the spirochetes in the aortic lesions. Decompensation of the heart is to be treated as in that of nonsyphilitic origin. Early diagnosis is imperative. There should be a greater willingness on the part of clinicians to make a tentative diagnosis of specific aortitis and a resort to a therapeutic test.

Sporotrichosis of the Genital Organs.—A. Brainos (*Paris médical*, March 20, 1920) reports two cases, both in young men, illustrating the fact that sporotrichosis may be localized upon the genitals and cause a septicemic reaction. In one of these cases the omission of potassium iodide in the anti-syphilitic treatment at first administered—without result—led to the thought that sporotrichosis might be present, for had the iodide been used from the first, prompt recovery would have occurred and a wrong diagnosis of syphilitic gumma probably have been made. Cultures showed the sporotrichum in this case, which recovered rapidly under potassium iodide by mouth and iodine-iodide solution locally. Whenever the physician administers the antisyphilitic therapeutic test in a case with a local lesion the syphilitic nature of which is confirmed neither by laboratory tests nor clinical study, potassium iodide should be omitted, in order to permit of differentiation between syphilis and sporotrichosis.

Comparative Study of the Wassermann Test and the Hecht-Weinberg-Gradwohl Modification.—A. J. Blaivas (*Journal of Laboratory and Clinical Medicine*, January, 1920) states that seventeen per cent. of the 100 sera examined had no hemolytic index, so that the Hecht-Weinberg-Gradwohl test could not be done. Nineteen cases showed a positive or borderline Hecht-Weinberg-Gradwohl test and a negative or borderline Wassermann. Of the fourteen of these cases in which the history was obtainable there was generally direct evidence of an early infection or of a mild easily overlooked case of syphilis or of a syphilitic association or consanguinity. In sixty-five per cent. of the cases the reactions were the same. Five per cent. showed a strong positive in the modified test, and a negative Wassermann reaction. An additional five per cent. were positive in tubes twelve and thirteen in the Hecht-Weinberg-Gradwohl test, and negative in the Wassermann, and four per cent. were positive in tube thirteen in the Hecht-Weinberg-Gradwohl test, and negative in the Wassermann. Blaivas believes that the Hecht-Weinberg-Gradwohl test should never be used alone to diagnose syphilis, but always in conjunction with the Wassermann test, and that a physician should be very wary in pronouncing a case syphilis when the modified test is positive and the Wassermann is negative. Blaivas's results are not in conformity with Gradwohl's claim that a complete inhibition of hemolysis is obtained in the Hecht-Weinberg-Gradwohl test, as he obtained several borderline reactions.

The Colloidal Gold Reaction with Cerebrospinal Fluid.—Ellis Kellert (*American Journal of the Medical Sciences*, February, 1920) considers the colloidal gold reaction to be useful as an additional or confirmatory test. It is of greatest value in the syphilitic diseases of the central nervous system, especially tabes and paresis, and it may serve to differentiate between tuberculous and other forms of meningitis. The reaction is correct in approximately eighty per cent. of cases. Cerebrospinal fluid contaminated with blood in small quantity frequently gives reactions in the luetic zone. Positive results unconfirmed by other tests are of only slight value. The Wassermann reaction and the cytological examination of the cerebrospinal fluid are of greater value than the colloidal gold test.

Contraction Waves in the Normal and Hydro-nephrotic Ureter.—Wilder G. Penfield (*American Journal of the Medical Sciences*, July, 1920) says that the ureter is a muscular tube which, when subjected to partial obstruction, always dilates, usually hypertrophies, and whose peristaltic rate is increased. Contraction waves pass in either direction with equal facility, depending on the location of the area whose rate of spontaneous contraction is most rapid. This area is normally in the renal pelvis, but abnormally a more rapid pacemaker may be established elsewhere. It is suggested that underlying the more rapid rhythm of the pacemaking area is the fact that its metabolic rate is more rapid than in any other level of the ureter. Production of a constriction ring which becomes pacemaker for the ureter above and below it depends on three things: the metabolic gradient, ureteral distention and refractoriness during contraction and the first part of relaxation. It is suggested that in the passage of a ureteral stone, trauma and inflammation increase the rate of metabolism in the ureter wall about the stone, a constriction ring results, followed by distention of the ureter and retroperistalsis. This would cause great distention of the renal pelvis and give to renal colic its peculiar rhythmical character.

Renal Manifestations in Heart Weakness.—O. Josué and M. Parturier (*Paris médical*, March 13, 1920) note that in heart cases with manifest signs of renal insufficiency there has been a natural tendency to ascribe these signs to actual renal disease coexisting with the cardiac disturbance. As a matter of fact, however, simple oliguria from heart weakness is sufficient to bring about a renal syndrome with azotemia or anasarca, and many cases classed as cardiorenal on the basis of both blood and urine examinations are not actually cardiorenal cases. Recognition of actual participation of the kidneys in the syndrome is not possible during the period of heart weakness and oliguria, but after digitalis has acted and diuresis become reestablished, the desired information may be secured, in particular with the aid of Ambard's ureosecretory coefficient. Often the kidneys are thus shown to be quite normal; or the kidneys may be slightly diseased, yet sufficient to eliminate urea so long as cardiac compensation persists. A high Ambard coefficient gives warning that in the event of loss of compensation,

prolonged oliguria will prove a more serious matter than usual. In all heart cases exhibiting a renal syndrome with oliguria, even though heart weakness is not pronounced, impaired renal function due to heart weakness should be thought of and heart tonics prescribed. Edema and oliguria are alike among the earliest and most reliable signs of cardiac insufficiency. Before the myocardium is toned up with digitalis, aqueous plethora must first be reduced by venesection and drastic purgation, which often relieve dyspnea at once and enable the patient to sleep. A milk diet should be ordered, and in cases with extreme oliguria, water alone allowed. Not more than 1,500 mils of fluid, with 100 to 150 grams of lactose, should be permitted in the twenty-four hours. Nativelle's digitaline in single daily doses of thirty to thirty-five drops is the best heart remedy for these cases. In grave cases, with persistent oliguria and increasing azotemia, such doses should be kept up for three, four, or even five days, in order finally to induce diuresis. When the latter does set in, the digitaline should be continued but gradually tapered down. Where oliguria is continuously threatening, digitaline may be advantageously kept up for some time in daily amounts of five to ten drops. Neither the albuminuria, azotemia, nor high blood pressure contraindicate the drug in these patients, but are instead benefited by it. Theobromine, 1.5 to two grams a day, may be combined with the digitalis or follow it. The salt free diet will assist in the removal of edema, but once the usual cardiac energy has been restored, salt may be resumed without causing edema to reappear.

Coxofemoral Arthritis Following Ingestion of Hexamethylenamine in Large Amounts.—Pierre Marie and Pierre Béhague (*Bulletin de l'Académie de médecine* May 11, 1920) report the cases of two men aged about forty years who, in order to escape from German prison camps, ingested massive doses of urotropin. Nearly 100 grams of the drug were taken in twenty-four hours, and in one case the total amount taken is estimated to have been one kilogram. In both instances marked and painful hematuria set in a day or two later, passing off two or three days after the drug was discontinued. Upon their return to France the men seemed to have completely regained their health, but in one instance ten months and the other eighteen months after the use of the drug there developed a progressive arthritis sicca of both hip joints, which became so marked that the patients could walk only with great difficulty and have remained thus incapacitated ever since. In one case x ray examination showed considerable changes in the head of the femur, which was irregular and presented cauliflowerlike masses projecting beyond the joint surfaces. In the other case the changes were less marked, but there were visible some ridges and irregularities completely surrounding the joint and the femoral head likewise showed deformity. The precisely similar effects in the two cases suggest that the drug was responsible for these joint changes. Experiments are being conducted to elucidate the matter and have already been attended with somewhat suggestive results.

Anomalies of the Bile Ducts.—Daniel N. Eisendrath (*Surgery, Gynecology and Obstetrics*, July, 1920) in discussing the possibility of injury to the bile ducts gives the anomalies which may occur as follows:

1. The gallbladder may be absent, rudimentary or hour glass; it may lie more or less completely enveloped by the liver (intrahepatic form); the pelvis may be on the upper instead of the lower side (reversed ampulla or pelvis); right hepatic duct may empty into the gallbladder; there may be transposition of viscera.

2. The cystic duct may be double, i. e., there may be two cystic ducts; the hepatic (right) duct may empty into the cystic duct; an accessory hepatic duct may empty into either the cystic or the angle of junction of the cystic and main hepatic ducts; the cystic duct may be so greatly dilated as to be almost indistinguishable from the main hepatic duct; the cystic duct may be very small and extremely short; parallelism (short or long) is present in seventeen per cent., and a spiral course of the cystic in eighty per cent. of individuals.

3. The hepatic ducts. There may be four or five instead of one main duct, which is formed just outside of the liver, and accessory hepatic ducts.

4. The common duct may be extremely short or very long; a double common duct may be present; in nearly ninety-five per cent. of individuals the common duct lies within the pancreas.

5. The blood vessels. There may be anomalies of the right hepatic artery; of the single cystic artery; of the double cystic arteries; and of the gastroduodenal artery.

Sliding Hernia.—Louis Frank (*American Journal of Surgery*, March, 1919) discusses sliding hernia and presents the following conclusions:

1. Sliding hernia (*hernie par glissement*) involving any of the abdominopelvic viscera is infrequently encountered, and sliding vesical hernia is the rarest type known.

2. Sliding hernia is noted with greater frequency in males than females in the proportion of about four to one; it usually accompanies inguinal hernia in the former and femoral hernia in the latter.

3. Sliding hernia seldom occurs in young subjects of either sex, those of middle and advanced age being most susceptible; but there are strange exceptions to this rule.

4. No viscus completely invested by peritoneum can become the sliding part of a hernia, in the absence of anatomic abnormality.

5. The anteoperative diagnosis of sliding hernia, irrespective of what may be the sliding viscus, is a physical impossibility.

6. The sliding portion of a sliding hernia cannot become strangulated, although strangulation of the true contents of the hernial sac is commonly observed.

7. The treatment of hernia, including the sliding type, is essentially surgical; and unless the nature of the pathological condition is promptly recognized and extreme care exercised in executing the operative steps, irreparable damage may be inflicted upon the sliding viscus.

Diabetes Due to Syphilitic Disease of the Pancreas.—P. Carnot and P. Harvier (*Paris médical* May 15, 1920) report the case of a woman aged fifty-three years, exhibiting both syphilitic nervous disease—beginning tabes and sacral anterior poliomyelitis—and diabetes with loss of weight and marked glycosuria. At the autopsy a syphilitic cirrhosis of the liver and fibrogummatous syphilitic pancreatitis were found, the latter process having resulted in almost complete disappearance of all pancreatic tissue. The clinical and pathological features were so clear cut as to establish beyond a doubt the occurrence of a form of diabetes due to syphilitic disease of the pancreas.

Urogenital Tuberculosis.—M. J. Latimer (*Urologic and Cutaneous Review*, May, 1920) says that urogenital tuberculosis is the most curable of the various forms of surgical tuberculosis; routine general and local examinations are essential to a correct understanding of all the associated factors and the definite localization of foci; the treatment of election is radical surgical procedure; accessible foci should be eradicated, even where radical elimination of all foci is impracticable; palliative surgery is especially indicated in advanced cases because it often is thereby possible to eliminate the almost constantly present factor of mixed infection and secondary toxemia.

Traumatism of the Spleen.—E. L. Connor (*Canadian Medical Association Journal*, June, 1920) says that ruptured spleen can only be treated as a surgical condition of the abdomen. Although the severe symptoms may be delayed, we should more often think of this condition in examining patients with histories of slight injury to the lower left thoracic region. Pain in the left shoulder, when no injury can be found about the joint, should at least be considered as being referred from the spleen. Splenectomy is not a difficult operation and should be undertaken by any man who has reasonable operating facilities. Ruptured spleen should always be considered as a condition demanding early treatment rather than postponed treatment at some large centre.

Fishscale Gallbladder.—John Ripley Corkery (*Annals of Surgery*, June, 1920) from a study of museum and fresh studies of so-called multiple small cysts of the mucosa of the gallbladder presents his conclusions as follows:

1. Multiple small cysts of the mucosa is a misnomer for this condition.

2. Fishscale appearance is due to chronic inflammation.

3. Lipoid substance leaves an apparent trail from the lumen of the blood vessel to the lumen of the gallbladder and is a constant feature in active cholecystitis in this condition.

4. Lipoid substance occurs in leucocytes in fishscale gallbladder.

5. The large polygonal cells in the submucosa may be transitional leucocytes.

6. The process of inflammation of the gallbladder is practically identical with inflammation of the appendix and barring mechanical difficulties the end result is the same, i. e., obliteration.

Proceedings of National and Local Societies

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-fifth Annual Meeting, Held in Chicago, May 24, 25 and 26, 1920.

The President, Dr. ROBERT L. DUNNINGTON of New York, in the Chair.

Analgesia and Anesthesia in Labor.—Dr. EDWARD P. DAVIS, of Philadelphia, stated that the best quality of ether, skillfully administered, was successful in the majority of cases of spontaneous labor during the second stage. If given at the height of the pain, quickly removed as soon as the pain subsided, it stimulated and did not retard labor, but the moment when expulsions occurred a few deep inhalations without air would render the patient insensible to pain although capable of comprehending sensations of feeling, hearing, or often of sight. The mother roused easily after delivery and required no anesthesia while the placenta was separating. For the insertion of stitches immediately after labor ether properly administered with oxygen was comparatively safe and efficient. He had seen no evidence that such use during the stage of expulsion injured the fetus. It was true that ether was inflammable, that some patients were excited by it, that it was irritable to the bronchial tubes and kidneys, and that it was difficult to anesthetize some patients with ether, but if skillfully administered it was usually successful and its combination with oxygen rendered it in his experience the safest of obstetrical anesthetics.

The modern anesthetizer should be prepared to use nitrous oxide and oxygen, ether and oxygen, chloroform with or without oxygen, changing, if necessary, from one to the other of these during a prolonged operation. In special fields of surgery the invention of special apparatus had made anesthesia vastly more accurate and successful. For the obstetrician analgesia or anesthesia, skillfully given, made for more accurate diagnosis during labor and for the successful management not only of spontaneous and normal parturition, but of complicated conditions. It was a familiar fact that recovery from parturition was greatly delayed by exhaustion during labor. In this regard modern analgesia and anesthesia were among the greatest advances made by modern obstetrical science. One must not forget the considerable fetal mortality and morbidity produced by prolonged birth pressure and by unregulated and violent expulsive efforts. The danger of asphyxia to the fetus during labor by analgesia and anesthesia was vastly less than the danger of hemorrhage from birth pressure and the avoidance of this latter complication was greatly enhanced by obstetrical analgesia and anesthesia.

Induction of Labor: Indications and Methods with Special Reference to the Use of Pituitary Extract.—Dr. BENJAMIN P. WATSON, of Toronto, Ontario, said that Blair Bell in 1909 was the first to employ in practice the results of experimental investigations carried out on the extract of the pituitary gland up to that time. Since then a great mass of literature had accumulated on the subject. It

was universally recognized that it was a most valuable agent for accelerating the second stage of labor when delay was due to feeble uterine contraction. In most of the articles which had appeared the reader was warned against using it for the induction of labor or before the cervix was fully dilated. He had used it extensively for the induction of labor and during all stages of labor, and had never had any bad results. In 1913 he recorded three cases in which he had successfully induced labor by its means. One of these was at the eighth month, one at full term, and one at three weeks post term. He stated that the method was worth an extended trial and he thought that his further results bore this out. The method used was to begin with a dose of one half to one c. c. administered intramuscularly with a long needle. In most cases uterine contractions commenced in about ten minutes and increased in severity during the next twenty minutes. At the end of this time the second injection of one half c. c. was given. If, after a time, the contractions tended to weaken, or to come at longer intervals, the dose was repeated. As many as six or eight doses might thus be given at intervals of about half an hour. The important point was to administer a further dose before the effects of the previous one had entirely passed off. The effects from a single dose appeared to last only for about half an hour and there was no cumulative effect. Sufficient doses must, therefore, be given to keep up uterine contractions sufficient to produce a certain amount of opening up of the cervix. When the cervix had begun to open and the membranes to bulge into it the uterine contractions would continue without the further administration of the drug. The failures which he had in the beginning were the result of not pushing the dose far enough. He had found it perfectly safe to give eight or ten one half c. c. doses at half hour intervals.

In nineteen multiparæ the average duration of labor was nineteen hours as contrasted with eighteen hours as an average in eighteen multiparæ. With the bag method the average time elapsing before labor began was thirteen hours and the average duration of labor was ten hours. This number, of course, was very small and not sufficient to draw conclusions from. With quinine alone, in twenty-five cases the average time elapsing from the last dose to the definite onset of labor was seven hours, while the average duration of labor was nine hours, seven for multiparæ and eleven for primiparæ. With pituitrin alone in a total of eighteen cases the average time elapsing between the first dose and the definite onset of labor was two hours. The average duration of labor was ten hours, sixteen hours for five primiparæ and nine hours for thirteen multiparæ. With quinine and pituitary extract, in a total of sixty-two cases fifty-three were successful and nine were totally unsuccessful. Six of the successful cases required repetition of the routine before labor began. In the fifty-three successful cases the average time elapsing between the first dose of pituitrin and the onset of labor was two hours and

the average duration of labor was ten hours; fourteen hours for twenty-three primiparæ and seven hours for thirty multiparæ. In the quinine and pituitrin cases labor was spontaneous except in four cases in which forceps were used when the head was on the perineum. In the total of fifty-three cases there were four stillborn babies.

Dr. Watson said that recently two of his colleagues, members of his staff, J. G. Gallie and W. A. Scott, had recorded a series of sixty-five cases in which they had used pituitary extract alone for the induction of labor. Out of this total number fifty-five were entirely successful. The average number of doses given was three and the average duration of labor was seven hours. There was one fetal death twenty-eight hours after delivery from atelectasis. The delivery was normal in forty-five, by forceps in nine and by version in one.

Taking these results with those which he had recorded, he thought we must recognize that the method had a definite place in obstetrical practice and should be considered before other methods were adopted. It had very special advantages in cases of slight disparity between the head and pelvis, as it did not in any way prejudice the Cæsarean operation should it prove to be necessary—an argument which could not apply to the bougie or bag method.

The Induction of Labor at Term.—Dr. CHARLES B. REED, of Chicago, said that labor could be inaugurated by quinine and pituitrin, by castor oil and quinine, by the modified de Ribes bag or by both. The castor oil acted in about two cases out of five and most reliably when the patient was a little bit past the calculated date. The Voorhees bag, in his experience, was the most dependable and was, therefore, the favorite agent at his hospital. The patient's bowels should receive attention the night before and in the morning the external genitalia given a careful obstetrical preparation.

Assemble and sterilize by boiling twenty minutes a modified de Ribes bag No. 4 (Voorhees), a Simon speculum or vaginal retractor, a pair of long Pean forceps (dressing forceps would serve), two pairs of volsellum forceps, two pairs of compression forceps, a Goodell dilator, a tenaculum forceps, a hand bulb syringe with glass tubes and rubber connections for the bag or a large piston syringe. The bag and accessory apparatus must be tested for defects before using. The patient prepared as for delivery was placed upon the table in exaggerated lithotomy position with legs held by assistants or by stirrups. The vagina was retracted, a smear made from the cervix and the mucous membrane wiped clean with pledgets. Anesthesia was only occasionally necessary even in primiparæ. One lip of the cervix was seized by the volsellum and brought down. If the bag had been properly prepared the os would admit it originally without dilatation. The bag must be emptied of residual air and the flat end pulled out. It was next rolled into a compact mass like a cigarette and seized by the Pean forceps so that the tips extended just to the largest diameter of the rolled bag. After anointing the bag with sterile glycerin it was passed into the cervix with the concavity of the

forceps turned toward the patient's left leg and as it entered the os the concavity was turned upward one quarter of a circle so that when the maneuver was completed the curve of the instrument conformed to the flexure of the uterus. Release the lock of the introducing forceps. Connect the tube of the bag with the filling apparatus and force the sterile solution (lysol, boric acid or plain water) slowly into the bag. Do not overfill by force or the bag will break. Tension in the tube of the bag or the feeling of resistance to the injection are signs of fullness to the experienced operator. If uncertain of the technic, a measured amount of fluid might be used. A piston syringe of tested size would also serve to inform the operator when the capacity of the bag (six ounces) had been reached. The Pean forceps were removed as soon as the bag was sufficiently filled to keep it from slipping out. Snap the compression forceps on the tube; remove the volsellum from the cervix and disconnect the syringe. Tie the tube of the bag strongly with tape. Remove the compression forceps. Place two sterile pads on the vulva, one on either side of the tube. Remove the stirrups and pull the patient up in the bed. The bag might break from overfilling or being insufficiently filled might slip out of the cervix before the uterine contractions began. If so, another bag should be inserted. If the pains did not start within an hour a weight of one or two pounds was attached by a tape to the protruding tube and passed over the foot of the bed. Usually in from five minutes to half an hour the contractions began and labor was under way.

In a variable period, rarely more than four hours (three hours and twenty minutes in his series) the bag was expelled by strong pains, the dilatation was practically complete and the head followed the bag down into the pelvis, the membranes ruptured and the second stage began. From then on the case was managed according to general obstetrical principles. The tedious, exhausting, and painful first stage had been definitely shortened. The bag acted as a mechanical aid to cervical dilatation, a dynamic stimulant to the contractions and it preserved the membranes from injurious pressure until physiological rupture occurred. When the membranes had been accidentally ruptured by the insertion of the bag no attempt should be made to pull on it to mark advancement lest it come out and by suction bring down the cord. When the bag came out after accidental rupture of the membranes at the time of insertion it was good practice to make an internal examination to discover the presence or absence of a prolapsed cord.

In the series of two hundred cases hitherto reported he had 114 multiparæ and eighty-six primiparæ. The average duration of labor was seven hours and fifty-six minutes; the longest labor was thirty hours, due to a tough, inelastic cervix. Two other patients were in labor twenty-eight hours from cervical conditions. In one the cervix was a mass of cicatricial tissue. The shortest labor in a multipara was fifty-five minutes and in a primipara sixty minutes. The bag broke while being filled or shortly after insertion nine times. Another bag was introduced four times. The mem-

branes were ruptured by the insertion of the bag seven times; in one case intentionally for hydramnios. The bag was expelled in an average period of three hours and twenty minutes. The longest detention was nine hours; the shortest was ten minutes. Two mothers died. One had myocarditis associated with a marginal insertion of the placenta. Her labor lasted only an hour and a half and was accompanied by a normal amount of hemorrhage only. Death came two hours after the delivery. The other had pneumonia and died eight days after labor. In no case did the bag fail to inaugurate contractions nor the woman to deliver.

The Prophylactic Forceps Operation.—Dr. JOSEPH B. DE LEE, of Chicago, stated that the prophylactic forceps operation was the routine delivery of the child in head presentation when the head had come to rest on the pelvic floor and the early removal of the placenta. Primiparous labors and those where the conditions of the soft parts approximated a first labor, were treated by this method, which really comprised more than the actual delivery of the child. It was a rounded technic for the conduct of the whole labor, with the defined purpose of relieving pain, supplementing and anticipating the efforts of Nature, reducing the hemorrhage, preventing and repairing damage.

Sir J. Y. Simpson said that labor, according to Nature's plans, should be normal, but that in a large proportion of cases it was not so. So frequent were these bad effects, that he had often wondered if Nature did not deliberately intend women should be used up in the process of reproduction, in a manner analogous to that of the salmon, which died after spawning. The radical interference with the mechanism of the third stage was intended to reduce the amount of blood lost, shorten the anesthetic period and reduce the danger of infection from retained blood clots, membranes and insufficient uterine contraction. He freely admitted that this method of treating labor was a revolutionary departure from time honored customs and must have really sound scientific basis for recommendation. This it had. First, it saved the woman the debilitating effects of the suffering in the first stage and the physical labor of a prolonged second stage, and in the modern nervous inefficient product of civilization, this was becoming more frequently necessary. The saving of blood had much to do with the quick and smooth recoveries he had observed in his cases. In the combination with morphine and scopolamine in the first stage, gas or ether in the second stage and operative delivery, one had robbed labor of most of its horrors and terrors, and the increase of the population ought to be thus favored. Second, it undoubtedly preserved the integrity of the pelvic floor and introitus vulvæ and forestalled uterine prolapse, rupture of the vesicovaginal septum and the long train of sequelæ. Virginal conditions were often restored. Third, it saved the babies' brains from injury and from the immediate and remote effects of prolonged compression. Incision in the soft parts not alone allowed shortening of the second stage, but it also relieved the pressure on the brain and would reduce the amount of idiocy, epilepsy, etc. The easy

and speedy delivery also prevented asphyxia, both its immediate effects and its remote influence on the early life of the infant.

The Value of the Wassermann Reaction in Obstetrics Based upon the Study of 4,547 Consecutive Observations.—Dr. J. WHITRIDGE WILLIAMS, of Baltimore, said that four thousand of the women were delivered between the twenty-eighth week of pregnancy and full term—1,839 whites and 2,161 blacks. In the series a positive Wassermann was noted in 421 cases, an incidence of 4.2 per cent.; 2.4 per cent. in whites and 16.29 per cent. in blacks; 302 children were born dead or died during the two weeks following delivery, and in 102, or 34.4 per cent. death was proved to be due to syphilis. Study of the 421 positive cases showed, 1, that the presence of a positive Wassermann did not necessarily mean the birth of a syphilitic child; and, 2, that efficient treatment instituted by the middle of pregnancy gave almost ideal results as far as the child was concerned. Observations proved that a negative maternal Wassermann did not necessarily imply the absence of syphilis, as shown by positive autopsy findings in twenty-two children. Study of the significance of the fetal Wassermann at birth and a comparative study of the diagnostic value of the Wassermann reaction and placental findings, also a brief discussion of the applicability of Colles's law was undertaken.

Extraperitoneal Cæsarean Section.—Dr. JOHN A. MCGLENN, of Philadelphia, stated that extraperitoneal Cæsarean section operations could be divided into two general types: a, The true extraperitoneal in which the peritoneal cavity was not invaded at any stage of the operation; this operation would be referred to as the extraperitoneal. b, The transperitoneal in which the peritoneal cavity was opened and subsequently isolated by attaching the parietal and visceral peritoneum and the uterus opened into this artificial extraperitoneal space; this operation would be referred to as the transperitoneal.

The advantages of the two types of extraperitoneal operation might be summed up as follows: 1. The peritoneal cavity, not being opened, was isolated from the field of operation, the danger from infection was less and therefore a better operation in the infected or supposedly infected case. 2. If the uterus ruptured at the site of the incision in subsequent pregnancies or labors it was an accident of no material consequence. 3. There was no danger from the formation of peritoneal adhesions. 4. The scar was not unsightly and the possibility of incisional hernia *nil*. 5. There were no postoperative intestinal complications. 6. Hemorrhage during the operation was slight.

His own feeling was that the Beck operation with thorough protection of the peritoneal cavity and perfect peritonealization of the uterine incision was superior to the transperitoneal operation as a routine procedure. While theoretically it was not as efficient as the extraperitoneal method, practically on account of the many disadvantages of the latter, it was the better operation.

THE RELATION OF THE MEDICAL PROFESSION TO THE CAMPAIGN FOR THE CONTROL OF CANCER.*

BY ROBERT B. GREENOUGH, M. D.,
Boston.

The developments of the last ten years have brought many new duties and responsibilities upon the medical profession in the way of public service. One of these responsibilities, the control of cancer, I shall consider in this paper, and while I refer to it as a responsibility I shall hope to show you that it is also an opportunity to accomplish an immeasurable amount of good, not only to your own patients but to the community as well.

We know from the figures of the statisticians that cancer causes the death of a very large number of our population—estimated at present at from eighty to a hundred thousand persons a year. We know that cancer is one of the most common causes of death of persons over forty years of age, and we know that in spite of the best efforts of the research institutions a sovereign cure for cancer has not yet been found, and that a radical surgical operation is at present our best and surest method for the complete extirpation of the disease. We know, too, that a relatively large proportion of cases of cancer are presented for operation too late to make it reasonable to attempt a radical cure of the disease. A recent study by Simmons and Daland of the statistics of the Massachusetts General Hospital show that of 519 patients with cancer of all varieties entering the surgical wards of the hospital for treatment only forty-four per cent. were suited even for the attempt to be made to accomplish a radical cure by operation. When we consider that the operative mortality diminishes this number further, we find that only thirty-eight per cent. of these 519 patients stood any chance whatever, of a radical cure. We must remember, also, that the results of any attempt at radical cure are problematical, according to the location of the disease, and the expectation of failure is in many regions greater than the expectation of success. It behooves us, therefore, as the health officers of the community, to consider this situation and do all that lies within our power to obtain a control of the situation which we do not now possess. Four

lines of attack present themselves at once for our consideration:

1. The education of the public to the early symptoms of the disease.

2. The instruction of the medical profession as to the actual facts of this serious situation to bring about earlier diagnosis.

3. The promotion of investigations on the part of surgeons in regard to more effective means of operative treatment.

4. The promotion of investigations in the laboratory in regard to the causes of cancer, and of methods of treatment other than by operation.

It is with the second line of attack that we are especially concerned, but a brief reference to what has been done in other fields may make our problem easier and better defined. The last ten years have seen a very marked difference in the attitude of the public toward matters of public health. A knowledge of disease has been obtained by the layman, far more accurate and intelligent than he ever had before. This is the result of the many agencies which have taken up the problem of educating the public for its own protection. Starting with tuberculosis and extending over such diverse subjects as baby hygiene and venereal disease, health matters have been given wide publicity, and topics never formerly mentioned in the lay press are now subjects of frequent notice and discussion. In this campaign of publicity the American Society for the Control of Cancer has had an important share, and it has been ably seconded by progressive health commissioners and public health officers who have seen the value of an educated public in relation to public health.

By the use of the lay press, the magazines—especially the women's and household magazines—by posters, by health department publications, through churches and women's clubs, and by the normal agencies for the spread of medical information, nurses and physicians, this education of the public can be brought about.

The facts which have to be impressed upon the public are relatively few and simple. The layman must be taught that delay is dangerous, that it is in the early and not the late case that the patient with cancer can be cured by operation, and that in early cases operation can, and does, cure many patients with this disease. It is an unfortunate fact that it is the failures and not the successes of the operative treatment of cancer that are known to the public.

*Presented before the Medical Society of the County of New York, May 24, 1920, and at a meeting of the Queens-Nassau Medical Society, Jamaica, Long Island, May 25, 1920.

Women who have been cured of cancer by an amputation of the breast or by a hysterectomy, do not allow even their intimate friends to know of the fact, but the death certificate rarely fails to indicate the cause of death correctly in unsuccessful cases. The public must be made to understand that unlike most other diseases pain does not occur as a symptom of early cancer, and they must learn that a lump or sore, or any abnormal discharge, especially if it contains blood, is a symptom in a person of cancer age which demands immediate and competent medical examination. It is asserted that a distinct improvement is already evident in those districts in which the education of the public has been carried on systematically, but there is a great deal more to do before the work is finished.

In this education of the public the physician must take his part, and it is an important part. The community of his own patients look to him for information on subjects of this character. Articles in the newspapers and magazines may arouse the layman's interest but it is his own physician to whom he appeals for corroboration. In the education of the public, therefore, the physician has a definite duty to perform. In the 519 cancer cases referred to, an average delay of five and four-tenths months occurred after symptoms were first noticed by the patient before he consulted a physician. Although the lapse of this amount of time is more serious in some cases than in others, it is far too long in any case for the best interests of the patient, and it must be shortened very materially and patients must be induced to consult their medical advisers much more promptly if we are to make progress in combating the disease.

By means of the instruction of the public we may confidently hope to bring the patient to his physician at an earlier stage of his disease. In doing this, however, we add enormously to the difficulties and responsibilities of the physician. It is a well established fact that the typical textbook symptoms of cancer of any organ are, as a rule, the symptoms of cancer that has extended beyond the possibilities of radical cure. If we wish to secure for every person afflicted with cancer the opportunity for cure to which he should be entitled we must abandon the textbook symptoms of advanced cancer and deal with the earliest symptoms of the disease. Under these conditions a positive diagnosis will often be impossible, and a method of dealing with these suspicious but doubtful cases must be made available. The first step, however, in this direction depends upon the examination of the patient. No sense of false modesty on the part of the patient or of indifference on the part of the physician should be allowed to interfere with the investigation by direct digital or visual examination, or with instruments if necessary, to obtain positive data for the establishment of a diagnosis. A Fabian policy of delay deprives a patient of an opportunity for cure, and thus signs the death warrant of many a patient who could otherwise be saved.

In the 519 cancer cases at the Massachusetts General Hospital to which I have referred, an average delay of three months occurred after the

patient first consulted his physician before operative treatment was advised. It is interesting to note the confidence of the patient in his physician's advice, for the average delay on the part of the patient after he had once been advised to undergo operation was only three weeks. It is clearly the duty of the physician to see that the patient's confidence in him is not misplaced, but we must admit that an average delay of three months at arriving at a diagnosis is far too long if we are dealing with a disease which progresses so rapidly as cancer does at this critical period of development.

In dealing with the group of early and doubtful cases of cancer the question of the exploratory incision and removal of tissue for microscopic examination becomes a serious one. The trend of the best surgical opinion is strongly opposed to any incision into cancer tissue when a positive diagnosis is otherwise available, on the ground that incision gives opportunity for an immediate spread of the disease. While this risk undoubtedly varies considerably with the location of the primary tumor there are some tumors in which the exploratory incision is successfully practised when a positive diagnosis cannot be made in any other way. There are other tumors, however, such as cancer of the breast or bone sarcoma, where a preliminary incision for the removal of tissue for examination, to be followed after a week or ten days delay by radical operation, is almost universally condemned. Such cases are best treated by incision and frozen section diagnosis when necessary, and the radical operation completed immediately, under one anesthesia. In fact, the use of the frozen section with immediate microscopic examination is probably the safest measure in any case where a biopsy is necessary to obtain a diagnosis sufficiently certain to justify the radical operation.

The term precancerous lesion is one which has been employed of recent years to indicate those essentially benign lesions which experience has shown appear too often as precursors of actual malignant disease. While the term is perhaps unfortunate in the sense that all lesions of this nature do not necessarily result in cancer, the frequent incidence of malignant disease in cases of this kind demands that treatment of these characteristic lesions be carried out with this principle in mind.

The lesions which commonly fall into this so-called precancerous group are as follows: Keratoses and papillomata of older persons, leucoplakia, fissures and sores of the lips, tongue and marginal mucous membranes, lacerations of the cervix, and benign tumors of the breast, thyroid and other organs. In this group, also, should be placed the pigmented moles which are so commonly distributed over the body, and which under any form of continued irritation are likely to give rise to the frightfully malignant tumor known as melanosarcoma. A very appreciable number of cases of cancer develop at the site of precancerous lesions of the type described. It is not open to doubt that the removal or destruction of the precancerous lesion would have saved the patient from the more serious disease. In this respect removal by surgical measures—generally an operation of the most minor

character—is the best method of treatment in that the total removal is accomplished and the tissue is made available for pathological examination. In this connection the establishment of a free diagnosis service for cancer tissue, by the public health departments of the states, or by the state universities, gives opportunity for the examination of such suspected tissue free of charge. Under these conditions the failure of a surgeon to submit the tissue removed for examination deprives his patient of the advantage of an accurate pathological report, to which, as a citizen of the state, he is entitled.

Where for any reason removal by surgical measures is not expedient, destruction of the lesion, if it is a small one, can be accomplished by the use of radium or x rays. This destruction, however, should be secured if possible by one vigorous and adequate exposure, for repeated irritation, either by radiation, by chemicals, or by any other agent, is to be strenuously avoided. It is by chronic irritation that we believe most of the so-called precancerous lesions are converted into cancer.

The operative treatment of cancer in its various locations has been so standardized in the operative clinics of the world that little opportunity exists for individual variation. This standardization has been brought about by the study of operating room and autopsy material which has shown the typical lines of extension from the original focus of the disease, which are characteristic and different for each of the common sites of cancer. Although the external incision may vary the anatomical structures removed are the same in practically every operating clinic for cancer in each of its common situations, and the general principle of avoiding by a wide margin the possibility of incision into cancer tissue at the time of operation is universal.

In a recent pamphlet issued by a committee of the American Society for the Control of Cancer these matters are discussed, and the standard operative procedure and the differential diagnosis of cancer in its many situations have been summarized. This pamphlet has been reprinted by the health commissioners of a number of states, and issued to every practising physician in the state.

While the operative treatment has thus been standardized it must be admitted that the prospects of success vary greatly with the different situations in which cancer most commonly occurs. While this variation is due, in part, to the rapidity of growth and extension of the individual tumor, it is determined even more by the anatomical situation in which the tumor lies, for this is the factor which limits the extent of local removal of tissue which can be sustained. We must hope, therefore, that further improvements in surgical technique may give us methods of attacking and removing the disease successfully in situations which are at present beyond operative attack.

Recent developments have shown that the combination of radium and x ray treatment with operation adds materially to our resources and gives promise of success in the treatment of certain cases of cancer in and about the mouth, and in other regions which with operation alone would of necessity be considered beyond hope of relief. In certain cases, also, the destruction of a local lesion may be

accomplished by the use of radium and the cautery accompanied by the subsequent dissection and operative removal of the regional lymphatics. In this way the attempt may be made to cure a certain number of cases which would otherwise be inoperable and beyond relief. In the line of development of these combined operative measures advances in the surgical treatment of the disease may confidently be expected.

In the many cancer research institutes of this country and abroad studies have been carried on looking to the discovery of the cause of cancer, its manner of growth, and the methods other than operation by which it may be expected to be cured. While none of these problems have been brought to a final solution many facts have been established of the greatest value in the treatment of disease. From the transplantable tumors of mice facts have been obtained which have determined both the advantages and dangers of the treatment of cancer by radium and the x rays. The fact that there is a degree of natural resistance to the growth of cancer tissue has been established. Experimental confirmation has been obtained to support the dictum that rough handling and massage of cancer tissue increases the rapidity of the spread of the disease, and it has been determined by the same means that the clean incision into cancer tissue for the removal of a specimen for microscopic examination is the safest measure to obtain a certain diagnosis when circumstances make a positive diagnosis necessary that is otherwise unobtainable. From the laboratories, also, evidence has been produced to show that the supposed relation of chronic irritation of one kind and another to the production of cancer is of great significance.

In the cancer research institutes many of the methods advertised from time to time as effective methods of treatment of cancer have been investigated. Many so-called cancer cures have been put before the public and new ones develop from day to day. Some of these measures are assumed to destroy the disease by biological methods, and others are of bacterial or chemical nature, but none has yet been found to be of sufficient value to justify its acceptance by the medical profession as a whole. It is the duty of the cancer research institutes, however, to continue the investigation of these suggested remedies, and to prosecute the search for *any* remedy which may be applied to advantage in the treatment of this disease.

There is no room to doubt that in radium and the x rays agents of the greatest value in combating cancer have been made available. While it is perhaps true that the first claims as to the successes of these methods of treatment were somewhat exaggerated a place has now been found for each of them, and in that situation they are productive of the greatest good. There is reason to hope, also, that further investigation of these two agents may make their value in the treatment of cancer greater even than it is at present.

In this brief communication I have tried to show that the situation in regard to cancer is at present a very serious one, and that it demands the best efforts of the whole medical profession toward its relief. While the first step must be taken by the education

of the public to the dangers of delay and the recognition of the early symptoms of cancer, more must yet be done to help the physician to recognize the disease in its earliest and curable stages, in order that his patient may have the benefit of such resources in the way of operation and other methods of treatment as the community affords. We must teach that the so-called precancerous diseases justify and demand treatment in prophylaxis of cancer, and, finally, we must support in every way we can the investigations which are being carried on in hospitals and in laboratories all over the world to improve the effectiveness of our methods of treatment of this insidious and frightful disease.

8 MARLBOROUGH STREET.

THE USE OF RADIUM IN ESOPHAGEAL CANCER.

BY HENRY HALL FORBES, M. D.,
New York.

The gloomy outlook for the patient suffering from esophageal cancer, and the gravity of the transthoracic operation with one cure to the credit of the procedure, the famous case of Dr. Torek (1 and 2), gave me a stimulus to use our available supply of radium in a series of cases in the nose and throat department of the New York Post-Graduate Hospital, where the director, Dr. Duncan Macpherson, has referred all cases to me. This has been done with my associate Dr. George Stuart Willis, who is in charge of the radium department of our institution and who has been in charge of the radium therapy, the aftercare, and the compilation of the results in our cases. Dr. W. H. Meyer, in charge of the department of röntgenology, has had control of this phase of our work. Both Dr. Willis and Dr. Meyer have been most conscientious coworkers and have made it possible to do this team work. Our thought was the possibility of giving to the patient and to radium a scientific standing, and now that nearly a year has passed I feel that the results warrant my bringing the facts to the attention of the profession for discussion and to stimulate other endoscopists to carry on and suggest modifications.

I cannot pass to the use of radium without a reference to the transthoracic operation for the cure of cancer of the esophagus, which is to my mind one of the most remarkable in the field of surgery. It was my good fortune to witness this operation as performed by Dr. Howard Lilienthal on a patient in Bellevue Hospital about a year ago, the surgery and skill of the operator being most brilliant. The result in this case was death. As far as I am able to learn the only cure credited to this operation is the case of Dr. Torek, who only a few weeks ago told me that the patient was living and enjoying good health, seven years having elapsed since the operation. It is well to remember that no transthoracic operation should be attempted until a specimen has been removed by esophagoscopy for pathological examination.

The results of the use of radium, with a rather indefinite technic was reported by Abbe (3) in 1914.

This covered work beginning in 1905, 750 cases in all being treated, which included 150 carcinomata of the tongue, larynx, and esophagus; the results were reported as excellent. Many patients had remained free from recurrences over several years and others showed remarkable improvement. Jackson (12) devotes considerable space in his book to cancerous growths of the esophagus. Note is made of his experience that the growths are usually single (which has also been my experience), and the importance of exercising care in passing the esophagoscope in these cases is emphasized. He has used radium, but does not appear to favor its use in operative cases. Relief has been given in the inoperable cases. Special reference is made to the necessity for direct application of the radium to the growth and to note the position of the radium tube by the fluoroscopic screen but evidently not carried out in his cases. The schematic representation of a radium capsule in the centre of an annular esophageal cancer is undoubtedly the ideal method and one we have attempted in our work.

We note other references to the use of radium and especially the technic followed by various authors. In 1914, Lewin (4) reports twenty-five cases with successful results, subjective symptoms, such as stenosis, improving in a short time. The radium or mesothorium was placed in a platinum or gold filter and covered with hard rubber; dose fifty to eighty mg.; exposure two to four hours, two or three times weekly for about five weeks. The radium tube was introduced by means of a hollow tube. No reference is made to an exact method of locating the radium other than the fact that it was held in place by a slender bougie. Further encouragement is given by the report of a case by Portis (5) in 1919 in which great improvement was noted in a case of squamous celled carcinoma where sixty mg. of radium were introduced into the stricture for two and a half hours. No details were given. Most interesting also were the cases of Pinch (7) from the Radium Institute of London, who considered that symptomatic treatment was better than gastrostomy, a patient taking food nearly to the end and being comfortable. Pinch (7) tabulates his cases in the years 1914, 1915, 1917, and 1918. In all he treated twenty-five cases of cancer of the esophagus, with the following results:

Improved, three; unimproved, five; dead, nine; abandoned treatment, three; results not noted, five.

The work in France has been taken up by Tuffier (8) who notes a case examined by the esophagoscope in which a diagnosis of malignancy was made. Direct application of the radium was impossible through the esophagoscope owing to extensive edematous inflammation. Gastrostomy was performed and when the patient had improved, the neoplasm was attacked by the transpleural route. The details are most interesting. It was possible to place a tube of radium emanation equalling one mc. in twelve hours against the growth for twelve hours. In this case Tuffier hopes, from the improvement noted in the growth, to continue treatments by the natural routes. This case is mentioned to show the resourcefulness of the worker and the improvement in what seemed to be a hopeless case.

*Read at the third annual meeting of the Association of American Peroral Endoscopists, at Boston, Mass., on June 1, 1920.

I cannot take up my personal work without referring to Dr. Janeway's book on *Radium Therapy in Cancer* (11). In addition to his work in radium Dr. Janeway is active in the work of direct examination of the esophagus and stomach. The cases reported in 1917 included twenty-two of esophageal growths; only one complete retrogression can be assumed. This patient, I am advised, was alive on May 6, 1920. The first treatment was given in June, 1916. Five other patients, now dead, were definitely improved; fifteen others were unimproved. His failures he considered due to the large size of the growth and the too frequent repetition of treatment. I am advised that Dr. Zwick, Dr. Janeway's assistant, states that the last year's work is much more encouraging, but that cases are too recent for one to give a positive report. Reports have been made recently by Japanese (9) and Spanish investigators (10), but it was impossible for me to obtain translations in time for this report. In February, 1920, Dufourmental (13), Paris, reported most encouragingly, noting cases in which the patients had been relieved from pain, swallowing had improved, and there had been a gain in weight. Patients had survived for more than eighteen months to three years.

As we read the various reports and note the therapy outlined it may seem that we are not presenting any new facts, yet I feel the corollary of our method of procedure has been an advance in the technic of the treatment of esophageal cancer by radium and that these very points may have been the cause of failures. Surely no one will doubt the results in the use of radium in cancerous growths involving the mucous membrane in accessible parts of the body. It must also be noted that unfortunately the esophageal growths are not productive of symptoms in the early stage of the disease and hence not discovered by the patient until the really grave symptoms become apparent and the disease has progressed to an almost inoperable stage. The operation by the transthoracic route in addition to its gravity, has as noted previously, only one living patient to testify to its merit. It does seem to me that it is our duty, in which we should be encouraged, to add to the details in the technic of radium treatment of this disease and not be discouraged in our work if we do not accomplish brilliant results at first.

In detail, our work has consisted of a full history with complete physical examination as well as blood tests. This is followed by a fluoroscopic examination of the esophagus using the barium salts as well as an x ray plate. With these data before us an examination of the esophagus is made in the operating room, usually under local anesthesia, using the Jackson esophageal speculum for the upper portion of the tube and the seven mm. or ten mm. esophagoscope to continue the examination downward. An attempt is made to note the local conditions. The placing of the radium tube in position has been the next problem; this has not always been easy. The radium tube to which a silk thread is attached is passed down through and out the lower end of the esophagoscope and held there by forceps while the esophagoscope is gently withdrawn a

short distance. Our idea has been to place the radium tube in the centre of the growth. The esophagoscope is then withdrawn completely. The silk thread prevents the radium tube advancing further downward by its attachment to a strip of adhesive plaster, which is in turn attached to the cheek. The patient is immediately taken to the x ray room where a fluoroscopic examination is made and usually a plate is developed at once. Should the placing of the radium tube have been faulty it is immediately removed and the operation repeated in forty-eight hours. The amount of radium is 25.5 mg. of a bromide salt. The tube is screened with .1 mm. gold and to absorb the irritating secondary rays about two mm. of pure Para rubber is used as a cover to the tube, which is usually left in place for twenty-four hours. The reapplications are made not oftener than once in three weeks. The blood picture is noted in this period. We are not in a position to claim cures, for our working time has been short, but we do feel that we have obtained symptomatic relief in all our cases and have added to the comfort and morale of our patients. The following is a brief summary of our cases: We have treated six cases of malignant disease of the esophagus, and the death of one patient is noted, hemorrhage being the cause of death.

[Since this paper was written the use of the radium tube has been abandoned and the radium needles substituted.—Author.]

Retroperitoneal Liposarcoma.—Edwin F. Hirsch and H. Gideon Wells (*American Journal of the Medical Sciences*, March, 1920) report the microscopical and chemical examination of a retroperitoneal liposarcoma without myxomatous elements, weighing sixty-nine pounds. It illustrated the capacity of malignant tumors to store up protein and fat, despite extreme emaciation of the patient.

TREATMENT OF ARTERIAL HYPERTENSION.

BY JOHN H. MUSSEY, M. D.,
Philadelphia.

Arterial hypertension is a subject about which much has been written in past years, as to the etiology, pathogenesis, and treatment. In spite of all that has been written and despite the facility with which medical men are accustomed to manage cases of hypertension, several new methods of treating this condition have appeared in the past two years and it is these newer methods that I wish to accentuate. First, however, it might be well to describe briefly just what we understand by hypertension, to present a general outline of the treatment for such high pressure, and then to discuss the more recent therapeutic innovations in the management of these cases, namely, benzyl benzoate and the restriction of salt and water intake.

Hypertension for which there is no obvious cause is a symptom, not a disease, and yet it is a symptom which is so closely related to disease that it is not amiss to treat the symptom, though as a general rule it is wise to observe the well known dictum "treat the disease and not the symptoms." A high pressure, though merely a manifestation of some underlying pathological process, is so frequently the main symptom and the cause of so many closely related symptoms that it has come to be regarded as a definite entity, no matter whether the increased blood pressure is the result of a nephropathy, an endocrine dystrophy, or a narrowing of the smaller elements of the blood vascular tree. Furthermore, by the ordinary clinical and laboratory tests, with which we are acquainted, in many cases of high pressure we are unable to demonstrate renal changes, internal secretory disorders, or other causes to explain the pathogenesis of the condition of high pressure. We are accustomed to assume in such cases that there is present a glomerular nephritis or a renal sclerosis, yet we are unable to show any distinct evidence of kidney pathology. This absence of symptoms and signs, except these referable to the high pressure, has led to a variety of names being applied to the syndrome. Janeway, because of the frequency with which such patients died a cardiac death, has labelled the disorder cardiovascular hypertensive disease. Allbutt has applied the term hyperpiesis to a group of cases in which elevation of the blood pressure is rather sudden and associated with many symptoms. Essential hypertension is the name most frequently applied to the disorder.

From this brief preliminary discussion of high blood pressure we may say that by essential hypertension we understand a condition of continuous high blood pressure, systolic pressure over 175 mm. of mercury, of unexplained cause. The patient may have many symptoms referable to the high pressure, yet on the other hand a high pressure may exist without symptoms and only be discovered accidentally when making a routine sphygmomanometer examination. Individuals of this latter type are not truly patients, yet the increasing incidence of disability and death from the results of high pressure and the likelihood of such

events taking place within a comparatively short time in the life cycle make such a person a patient, one who requires treatment. He is objectively though not subjectively sick.

General treatment.—In the management of cases of hypertension it must not be forgotten that the hypertension is a compensatory process and that any efforts to reduce suddenly the pressure by drugs, bleeding, and so on should be avoided, unless there is a threatened apoplexy or some such catastrophe imminent. Active measures are to be avoided unless absolutely necessary, and the pressure should be reduced slowly. Fortunately, Nature in her kindness has so ordained things that it is extremely difficult to reduce pressure at any time and more than difficult to reduce it suddenly. This is indeed a blessing for many are the attempts to lower suddenly a high pressure where success would lead to cardiac failure or to uremia. But in most cases the gradual reduction of the pressure is distinctly indicated, if for no other reason than to relieve the heart of a tremendous amount of unnecessary and harmful work.

Diet.—The first step, and probably the most important in the handling of these cases, is the correction of faulty habits of life and notably the correction of the more than probable abuse of food. Overeating is to be avoided. Probably overeating has induced high pressure more frequently than any other single cause. Food should be taken at regular hours, eaten slowly, and should be followed by a short rest of fifteen or twenty minutes, as the pressure rises during and immediately after eating. Alcohol should be avoided and tobacco should be used moderately. The protein foods should be eliminated from the diet to a great extent. Animal foods form the great bulk of the proteins and it is these foods that should be restricted. Fish, white meats, and eggs are as culpable as the long condemned red meats in the production of harmful nitrogenous waste products, so it is of little value to tell the patient to reduce one type of protein while he is given tacit permission to go as far as he likes with other types. One small slice of meat a day should suffice the patient suffering from hypertension. Milk also should be taken moderately in chronic cases, whereas using it as a food alone, one thousand c.c. a day for several days, will reduce a pressure which has been found resistant to all other means.

Physical effort.—Excessive physical effort is to be avoided, by all means. Work should be much restricted and outdoor recreations should not be too strenuous. A certain amount of physical effort and exercise is advisable, however, as it aids the proper elimination of toxic waste products and brings about a healthy metabolic increase. Sudden severe violent physical effort is especially to be warned against.

Hurry, worry, and mental strain.—The patient with high tension should avoid mental stress and strain. The hurry of present day life, the worry incidental to so many diverse factors in business, and the mental strain accompanying such hurry and worry are distinctly to be avoided. The hypertensive patient should cultivate a calm, lethargic mien, if possible.

Sleep and rest.—During sleep the pressure falls most decidedly and the same applies to absolute rest in the recumbent position. The patient, therefore, should be instructed by the physician to obtain a good night's rest and when insomnia prevents this, some of the mild sedatives should be prescribed.

Elimination.—In these cases the bowels should be kept well open. One or two good loose movements a day should be secured by a morning saline purge and once or twice a week calomel or blue mass should be taken, or the mercurial may be taken when the symptoms of hypertension are particularly annoying.

Hydrotherapy.—It is my custom to order for my patients electric cabinet baths twice a week. In my dispensary patients this is obtained in the hydrotherapeutic department of the University Hospital. Elimination through the skin may be aided further when it is impossible to get the cabinet baths by having the patient take Turkish baths once or twice a week and follow this with mild exercise. When hydrotherapy of this type is unobtainable I recommend a prolonged warm bath for fifteen minutes at a temperature of 103° F.

Drugs.—It has been shown conclusively that drugs are of little value in combating high pressure over any length of time. The iodides are of value only in syphilitic cases. The nitrites produce a temporary fall in pressure only and a tolerance to them quickly follows their prolonged use. They should be reserved for emergencies. Radium charged water has not been followed by any particular action, as far as I could determine in the few cases in which I have employed it. Of the newer drugs benzyl benzoate has received particular attention as a reducer of blood pressure.

This drug was introduced by Macht in 1918 and came into general use in the fall of 1919. Benzyl benzoate is one of the so-called minor alkaloids of opium and was isolated by Macht during the course of his study of these alkaloids. He discovered that these preparations have a marked relaxing action on the unstriated muscles of the body and are capable of relieving spasm of such muscle. On account of this antispasmodic and tonus lowering effect Macht had the drug tried out in a variety of conditions which are associated with muscular spasm. He asserts that he received good results in relieving the following spasmodic conditions: Diarrhea and dysentery, intestinal colic and enterospasm, pylorospasm, spastic constipation, biliary colic, ureteral colic, vesical spasm, spasmodic pains in seminal vesicles, uterine colic, bronchial asthma, and arterial spasm hypertension.

It is with this last condition that we are particularly interested today and I will recount to you my rather brief experience. In a small series of six cases I religiously gave the drug for some weeks. In order to test it out I used but few auxiliary methods but rather made an effort to see if the benzyl benzoate, plus a few simple general hygienic directions, would lower the pressure. In no case did I see any effect from it whatsoever. Likewise I have talked with some of my colleagues and they have been almost unanimous in expressing the

opinion that it has but little effect on the blood pressure.

While I have seen little if any result from the administration of benzyl benzoate in the treatment of increased blood pressure I have had the opportunity of testing it in two cases of angina pectoris and can testify as to its value in this condition. Likewise in several other painful or disagreeable spastic conditions its action has been truly remarkable.

Reduction of salt and water intake.—Some months ago Dr. F. M. Allen published an article (1) on arterial hypertension in which he advocated the reduction of water intake and the elimination of salt in the treatment of hypertensive cases. Allen's thesis is that in many cases high pressure is a compensating process in which the elevated pressure is necessary "to force a filtrate of water and dissolved substances through a damaged and partially blocked glomerular filter." His theory, while not a new one, has never received much attention in this country or Germany, though to a certain extent the French school has recognized the coexistence of high pressure and salt retention. Allen shows by his results that there is a very definite relation between salt retention, large water intake, and high pressure. To determine the value of this procedure we have observed, in the medical dispensary of the University Hospital, the effect of the lowering of salt and water intake upon patients with arterial hypertension, not caused by obvious renal disease. Likewise in three private cases I have had the opportunity of watching the effect of this treatment upon the blood pressure. Though there are only seven cases to report upon and it is unwise to draw deductions from this small series, nevertheless as the results were so uniform, it does not seem unfair to present them.

	BLOOD PRESSURE.			
	Before Treatment Systolic	Diastolic	After Treatment Systolic	Diastolic
Case I.	185	85	125	75
Case II.	215	105	170	85
Case III.	157	79	130	80
Case IV.	204	115	170	105
Case V.	205	120	160	100
Case VI.	174	80	145	75
Case VII.	230	110	210	100

In the dispensary cases studied by Dr. Robert McMillan repeated examinations were made of the blood urea, plasma chlorides, and phenolphthalein elimination. He found that the plasma chlorides were raised before reducing the salt intake and that the reduction in chlorides was commensurate with the lowering of the salt intake. Likewise the height of the pressure had a fairly definite relation to the plasma chloride fall. In order to illustrate more satisfactorily the result of this treatment I will recount briefly the history of a patient I have treated with potassium iodide and sajodin, and subsequently placed upon a modified restricted salt free diet.

CASE.—Mrs. M., aged fifty-three, widow. Patient referred on account of gastric symptoms. Except for the gastric symptoms, ringing in the ears, nycturia once a night, and an intermittent heart, she had no other complaints. There was no edema nor dyspnea. In her past history there was noted eclampsia sixteen years ago and hysterectomy nine years ago. The family history showed that her

mother had died of apoplexy at the age of seventy-one, and one brother of nephritis and apoplexy at fifty-six.

Examination showed a rather well nourished female; eyes, teeth, tonsils, and thyroid negative; lungs clear; heart enlarged down and left. There was heard a presystolic mitral murmur, a much accentuated aortic second sound, and an occasional extrasystole. Abdominal examination showed nothing but a slight ptosis of the stomach. The gastric examination showed a marked subacidity. The urine in repeated tests showed a specific gravity varying from 1008 to 1024. Occasionally a trace of albumin was found. The preliminary blood pressure was 205-120, the hemoglobin ninety per cent. The eye grounds were negative.

The patient was ordered sodium phosphate daily, prolonged warm baths twice a week, a low protein diet, and was given general directions as to daily hygiene. In a short time iodide of potassium was ordered and subsequently sajodin. For a month the pressure ranged between 205-190 systolic, 120-110 diastolic. At the end of this time, when the pressure was 205-115, the patient was suffering very much from dizziness and tinnitus. She was ordered to cut out salt from her dietary and restrict water to 800 c.c. a day. Eight days later the pressure was 185-105; in nine subsequent examinations it had fallen steadily until at the present time it is 160-100. The patient is now practically free from symptoms and is apparently in good general condition.

There are several minor observations I would like to make upon this phase of the treatment of hypertension. If a reduction in salt intake is ordered, the need of the organism for water for the purpose of diluting the increased chlorides retained in the body is not pronounced. Therefore, with the reduction in the salt the desire for water is decreased and the water intake is almost automatically diminished. The estimation of the plasma chlorides gives positive evidence of the reduction of these salts which is confirmed by the blood pressure observations. While the plasma chloride estimation is of great value and should be used whenever possible in treating the hypertension patients, nevertheless the parallelism of the reduction of the pressure and the chlorides is so close that by simply following the blood pressure a fairly accurate idea may be attained as to the actual reduction of the plasma chlorides when laboratory facilities are lacking. Lastly, it must not be supposed that all cases respond to this form of treatment, as, for example, Case VII in the table.

CONCLUSION.

The management of a case of hypertension requires a careful study of the patient. Unless some threatened vascular cardiac or renal catastrophe seems imminent physical and hygienic measures should be relied upon more than drugs. The reduction of salt and water intake forms a valuable adjuvant to these measures.

WHAT IS DISEASE?

BY CASPER L. REDFIELD,
Chicago.

In a work on pathology, health is defined as "that condition of function and structure which we find to be normal," and disease is defined as "any departure from the normal standard of structure or function of tissue or organ." At the same time the "normal" is defined as that which "we find to be the commonest." In other words, the average of function and structure is taken as the normal, and any departure from that average is designated as disease. Under that definition, the champion pugilist, the champion wrestler, and the champion oarsman would be diseased men. The champion trotter would be a diseased horse, and the dairyman who kept specially good milkers should be prosecuted for selling milk from diseased cows. And men with such robust intellects as Newton, Franklin and Edison must have diseased brains. At some time in the past, man's ancestor was much more apelike than manlike, and to get human beings from such ancestors there must have been departures "from the normal standard of structure and function." Under the definitions quoted, the entire human race must be a diseased product. And what is more, evolution must be a disease.

The object here is to present a new definition for disease, and to indicate some of the reasons why it is thought that this new definition is superior to the old. This new definition will include among diseases some things not now considered as disease at all, and perhaps will exclude as not being disease some things now considered as disease. The real object of presenting the new definition is to cause disease to be looked at from a new angle, and such new view will be instructive even if the reader does not agree that the definition is of the proper scope. As a convenient procedure, the definition will be given first and the argument later.

Disease is the effect produced upon certain cells or organs by a continued overload, which, if not interrupted, results in the death of the cells or organs. The term disease might, with propriety, be used to represent both the overload and the result produced by the overload. It might also be used to represent the process by which an overload destroys life. In this last meaning, the definition would be reduced to the epigrammatic form

DISEASE IS THE ROAD TO DEATH

Under these definitions, nothing could be called disease unless it led toward death, either of the individual, or of certain cells or organs in the individual. A mere stress or strain which caused pain and abnormal action within an organ would not be disease unless the magnitude of the stress or strain were sufficient, if continued, to cause the death of some of the cells within the organ. A deformity, while it might be the product of a disease, would not be a disease itself unless it were of a kind which would necessarily cause death. In such a case, the deformity would be the overload. Or a deformity plus something else might amount to an overload, in which case the deformity would be a part of it.

Let us suppose that I should stab a man in the arm, or leg, or back, and he should lose considerable blood before the flow could be stopped. He would be weakened by the loss of blood. Suppose that the next day, before he had been able to recover from the loss he suffered, I should stab him again, and he should lose still more blood. Suppose further that day after day I should stab him in the same way and that day after day he became weaker and weaker until he finally died. No one would say that the man died as the result of disease.

Suppose that a man traveling in a tropical jungle should find leeches so numerous that he was unable to protect himself, and that day after day they drew so much blood from him that he finally died. This is not disease under the ordinary meaning of that term. But let us suppose that unknown microorganisms cause increased destruction of blood corpuscles day after day until the man dies of anemia. That is disease.

Wherein do these things differ in their essence? In each case the man dies from blood losses day after day. Are we to use the term disease to represent only the mysterious and the unknown? Small leeches taken in drinking water sometimes attach themselves to the fauces, and the effects produced have been mistaken for disease. Does a disease cease to be a disease as soon as we understand it?

Suppose that a man is bitten by scorpions or by tarantulas, or is stung by bees, wasps or hornets until he becomes seriously ill as the result of the poison injected into him. No one says that such illness is due to disease. If a man is similarly poisoned by typhoid or pneumonia or other germs, that surely is disease, but wherein is the difference? Is the first not a disease because it is by some familiar insect, and the latter a disease because it is by some unfamiliar bacterium? Is the question of disease and not disease to be determined by the factory in which the poison is manufactured rather than by the nature of the poison and the effect it produces?

In several cases it has been discovered that stags, in fighting, have got their antlers locked together and have died in this condition. We can picture the combat with the horns locked. The deer can struggle only by pushing and pulling and twisting. They cannot produce any wounds upon each other. But in that pushing and pulling and twisting they wear themselves out and finally fall down and die from sheer exhaustion. Did those animals die as the result of disease?

When a person is worn down or exhausted from long continued physical exertions he is much more susceptible to bacterial infection than when not so exhausted. Also, after a man has been through a long illness due to some bacterial infection, he is worn out and weak. These are facts which show that the same energy used in a physical struggle is the energy used in fighting bacterial infection. The burden thrown upon a man's powers by bacterial infection is called disease, but the similar burden thrown on the same powers by an opponent or by some physically observed and fully understood circumstances is not disease. But wherein is the difference? In both cases the physical powers are ex-

hausted by efforts which expend energy of the same kind. Does a disease cease to be a disease when the millions of cells which a man fights are organized into large bodies instead of being separate entities?

We can convert work fully and completely into heat, but we can make the reverse transformation only in part. As a consequence, heat is called the degraded form of energy, and is always a product of work performed. When a person takes violent exercise, as in a foot race or a wrestling match, his temperature increases and may rise to 105° F., or more, and such appearance of extra heat is evidence of the exertion he makes. A fever represents an increase in the heat form of energy and is evidence of a physical struggle of some kind which is invisible because it is within the body. The invisible struggle which produces a fever is said to be disease, and the visible struggle of a foot race which correspondingly raises temperature is not disease. Is a question of disease to turn upon the degrees of visibility? Is a bacterium to be considered as the cause of disease because he can be seen only with a microscope, and an opponent in a wrestling match not the cause of disease because he can be seen with the naked eye?

When a man swings Indian clubs or dumbbells he exercises certain muscles and expends certain foot pounds of energy. As the swinging continues, he gradually becomes tired and has to stop for a rest. After resting for a few minutes he can resume his exercise, but soon becomes tired and must rest a second time. After another short rest he can begin the exercise a third time, and so on time after time for perhaps several hours. Each period in which the man was taking this exercise consumed the available energy in the muscles being exercised, and during each period of rest the supply in the exercised muscles was partially replenished by drawing upon the store existing at the time in other organs.

The fact that severely exercised muscles in the arms may draw upon the reserves in unexercised parts of the body is evident from the fact that a person who has become tired by swinging dumbbells is in no condition to compete in a foot race or in a debating contest. Each organ has in it a store of energy normally appropriated for the use of that organ, but in emergency, a severely taxed organ may draw upon the supplies in other organs. An organ so taxed is suffering from an overload during the time when the efforts are continued. But if the man rests until the next day, or for a period long enough for his system to get back into the organs from the food supply the amount equal to that expended, then there is no overload when the efforts are measured in the longer period. The overload was interrupted by the rest. If not interrupted, then the man would ultimately die from exhaustion as in the case of the deer with locked horns.

When a man goes into a gymnasium or out onto a golf course and takes more exercise than has been customary or habitual with him, but an amount which is less than an overload when the resting time is counted with the exercising time, he builds up the energy supply in the exercised organs to something

greater than it was before. If he begins such exercise comparatively early in life and keeps it up regularly, he may develop his powers to something much in excess of anything he inherited. Examples of such development may be seen in the trotting horse. In the evolution of the two minute trotter from stock not capable of trotting a mile in three minutes, many thousands of the horses trained and raced have developed trotting powers much in excess of anything which ever existed in any ancestor. In this connection the reader should remember that the run is the natural high speed gait for the horse, and that high speed at the trot is an artificial product of the nineteenth century.

The reverse of the development of powers by exercise is the degeneration of powers by idleness—the term idleness meaning an amount of exercise to the unit of time which is somewhat less than has been habitual. In previous articles (1) I have given many examples of the development of powers by exercise and the degeneracy of powers by idleness in animals, plants, bacteria and protozoa. A few more examples will be given here.

Pasteur found that the anthrax bacillus could be raised on an artificial medium, as bouillon at blood temperature. When so raised the bacilli do not have to fight for life in a hostile blood reaction, and because they do not have to fight they gradually lose their power of fighting, which is their virulence. He used two cultures, a very weak one produced by a long period of idleness in life on artificial food, and one not so weak produced by a shorter period of idleness. He then inoculated an ox with the weaker culture, and twelve days later with the stronger culture. An animal so inoculated was immune to fully virulent virus. Here we have the progressive decay of powers in the bacilli by idleness, and the progressive development of powers in the ox by exercise.

But Pasteur's experiments went still further in this matter. By long cultivation on artificial food he got anthrax germs so weak from the lack of exercise in fighting for food that they were unable to survive even in a mouse. But by taking such weak virus and inoculating a very feeble animal, as a guineapig a day old, and then passing it along by inoculation to stronger and stronger animals, he found that the strength of the virus was built up step by step with each inoculation until it was powerful enough to attack the strongest animals. Here we have a case of absolute control over the gain and loss of powers in the same organism by controlling the amount of its exercise.

Haffkine made similar experiments with the cholera vibrio. This is a motile organism, the virulence of which seems to be directly proportional to its power of movement. He found that, for the two inoculations he wanted to make to produce immunity, the germs obtained from the intestinal canal were too powerful for the preliminary inoculation, but not sufficiently active for the second, if marked protection was to be obtained. He also found that by growing this germ on agar, or other nutrient media, it gradually lost its activity and virulence, and he could thus get a weak form suitable for the first inoculation. Also, he found that

by passing germs from the original stock through "a series of about thirty guineapigs" he got a virus of "great activity."

Here we have a case of producing two strains of microorganisms from the same stock—one a weak strain which gradually lost its powers because it did not have to exert itself by a struggle for existence in a hostile environment, and the other a superpowerful strain which became such by being compelled continually to exert itself by passing from hostile environment to hostile environment for about thirty times. These two strains formed the weak and strong vaccines which he used successfully to make guineapigs immune against doses of cholera poison from eight to ten times the normal lethal dose. But he found one thing more. He found that after he had got the powerful culture he must maintain it by the process by which he obtained it. On agar, the powerful germs soon lost their activity, and it was necessary, from time to time, to pass them again through a series of guineapigs.

Without multiplying examples of cases in which the powers of living organisms have been increased or decreased at will by causing those organisms to either exercise or fail to exercise the powers they have at the time, we may consider what overload is in bacteria. When Pasteur got anthrax virus so weak that it could not survive in the blood of a guineapig a month old, the powers of the guineapig were an overload for those germs. But when he came down to something as feeble as a guineapig a day old, then those weak germs were an overload for that young guineapig.

Now the difference between a guineapig a day old and a guineapig a month old is a difference in physical powers developed by normal activity in the interval between a day and a month, and not a difference in inheritance. Guineapigs do not do any inheriting after they are born. A load is measured by the powers necessary to carry it, and as powers increase or decrease in accordance with the extent to which they are exercised, it is evident that what may be an overload at one time may not be an overload at another. Also, powers may be decreased by simply shutting off the power supply, in which case a load which was less than an overload might become an overload. For example, a load which a person could carry with ease and not even be aware of its presence might become an overload by reason of an insufficient supply of food, or of some ingredient of food. An animal weakened by starvation is more than normally likely to fall a victim of some disease.

If a man exercises the muscles of his arms and not the muscles of his legs, his powers are developed in his arms and not in his legs. If his work is mental exercise and not physical exercise, then powers are built up in the brain and not in the muscles. If a man begins by taking small doses of arsenic and later becomes an arsenic eater, he develops his powers of resisting arsenic and not those of resisting opium or some other drugs. When a person is vaccinated his powers of resisting smallpox are developed and not those of resisting pneumonia or some other disease. And so on.

While these things are relatively true, they are not absolutely true. When any kind of powers develop in a person by exercise without at the same time permitting some other powers to decline by idleness, the total powers in his organism are increased, and the total supply may be called on for assistance when some particular organ is overloaded. This is illustrated in the case of the dumb-bell exercise previously given. It is further illustrated in the case of snake venom, for which no animal has normally developed a specific resistance. But by beginning with small doses insufficient to cause death, and then gradually increasing them, a few doses have been sufficient to enable an animal to withstand, without harm, a dose fifty times as great as would have been fatal in the first instance. Such great development of some specific power in a short time can be obtained only by the conversion of some powers already within the system.

If a man is attacked by smallpox or pneumonia or other equally dangerous ailment, and then recovers, is the attack a disease within the definition here given?

Yes. It is a case of an overload which was continued for a time but failed to produce death because it was interrupted. The fact that there was an attack which caused distress is evidence of an overload. A load which is carried easily is not an overload. For example, the heart carries a load from birth to old age without difficulty or distress, but let there be a considerable increase of blood pressure, and the load becomes an overload. An attack of smallpox is possible only because the system does not have in it enough of that specific form of power which resists this kind of germ. In attempting to meet this form of attack the system builds up its resisting powers by exercising them and by calling on other powers for help. When these resisting powers become greater than the powers of attack, the overload passes from the man to the germ, and the germ not having outside powers it can call upon for help is quickly destroyed, and the man becomes convalescent. In this proceeding the man's resisting powers have become very great at the expense of other powers, as is evident from the fact that a convalescing man is physically weak.

526 MONADNOCK BUILDING.

Study of Wound Healing in the Rat.—Hachiro Akaiwa (*Journal of Medical Research*, September, 1919) studied wounds of various kinds in the skin of the ears of rats, produced with trocars or razors. A detailed description of the results obtained is given. Among the conclusions arrived at by Akaiwa are the following: The shallower the wounds, the more rapidly the new epidermis enlarges, which is due to the smooth wound surface, over which the epithelium moves with little resistance. The larger the wound the more rapidly the new epidermis enlarges, so that larger wounds close relatively more rapidly than smaller ones, and shallow wounds more quickly than deep ones.

THE DOCTOR AND THE NEUROPATH.

BY CHARLES R. BALL, M. D.,
St. Paul, Minn.

Various comments which my colleagues have made with reference to hysterical and neurasthenic patients, as well as an experience with a multitude of such patients who have gone the rounds, are some of the reasons why I have chosen this subject. A remark not infrequently heard is something like this: "I do not know a thing about nervous diseases," and then there is often added, as if in self-defense—"And I am rather glad of it."

If I were a Freudian, I would be inclined to consider such expressions on the part of my confrères as symptomatic of past embarrassing and unsatisfactory experiences with these patients which they have endeavored to bury in their unconsciousness but which from time to time tend to symbolize themselves in this manner.

This reaction of the doctor to the type of patient described is not without its justification from his viewpoint. In his examination of them they had passed the acid test. Their temperature, pulse, blood pressure and urine examinations were normal. The bismuth meal and fluoroscope examination showed that their gastrointestinal tract was performing normally. The absence of anything definite or positive in either their physical or laboratory findings forced the doctor to the conclusion that these patients, for whose numerous and diverse symptoms he could find no adequate or tangible explanation, which often increased rather than decreased under his ministrations, were simply victims of their own imagination and that nothing really ailed them anyway. In the end he usually dismissed them with the parting injunction to "go home and forget it."

During my early days of practice, the term neuropath was neither as much in vogue or as well understood as it is now. Neurasthenic and neurasthenia were the expressions used in referring to the functional nervous type of patient. The rest cure of Weir Mitchell was then at the height of its popularity with the nerve specialists as a successful means of treating these cases. The neurologist in making use of the rest cure was carrying out a logical method of therapy according to the understanding which he had at that time of his patient's malady. The best conception of neurasthenia was that of a nervous exhaustion—pure and simple. The state of mind, the attitude of the patient himself, as an important contributing factor in the causation of his symptomatology received little or no consideration.

When we reflect on this conception of neurasthenia and the manner of treating it by the neurologist, we must admit that at this time he had little to boast of in his methods over those of his medical colleagues—the surgeon and the internist. The improvement observed in so many cases by patients who had taken the rest cure was also noted by the surgeon after many of his operations, testified to by thousands who had drunk of the waters of Lourdes, gazed reverently on one of the bones of St. Anne, experienced the laying on of hands of magnetic healers, worn electric belts and undergone numerous

other both mystic and mysterious procedures. Their faith, if it had not made them entirely whole, had worked wonders for them. Autosuggestion and heterosuggestion were chiefly responsible for their improvement.

The neurasthenic has always been a *bête noir* to the medical man. He can point with pride to his progress and accomplishment in almost all other directions but at the feet of the neurasthenic he is compelled to acknowledge his Waterloo.

What may be considered as a rational explanation of this thus far baffling patient? In regard to his etiology, we realize more clearly than formerly that the neuropath, like the poet, is more often born than made. We see in him an individual with a nervous diathesis, which is inherited and inherent, just as truly as the diathesis of the patient of whom we speak as being rheumatic, hemorrhagic, gouty or strumous. We also recognize that the neuropath is closely akin in the genesis of his condition to a large number of other mental and nervous diseases also called functional in origin—as for example, migraine, epilepsy, dipsomania, angioneurotic edema and the various psychoses.

Often one of these other conditions, such as migraine, is found in the neuropathic individual as a further proof of his nervous dyscrasia and complicates his neurasthenic symptoms. The affections which I have just mentioned are regarded as both physiological and psychic stigmata of this nervous diathesis and may be considered as interchangeable with one another either in the same individual or more especially some member of his family. As illustrative of this, the father of a neuropath, instead of being, strictly speaking, a neuropath himself, may have exhibited this predisposition as a dipsomaniac. A neuropathic mother may have passed on her nervous dyscrasia to some one of her offspring in the form of an epilepsy and so on. All these types of functional nervous affections have been classified under one great group, called the psychoneuroses. The important thing which I wish to emphasize in the consideration of the neuropath is that fundamentally and physiologically he differs from the normal individual and in judging him in a spirit of fairness and also from the viewpoint of his welfare, his past is just about as pertinent as his present. He has an inherited tendency to neurasthenia and so called neurasthenic symptoms which the normal person does not have, or if he has, not to what may be called the pathological degree of the neuropath. Such stigmata as he exhibits, such as migraine, irritability of the vasomotor system, as seen in the rapidity of his heart beat, the coldness and clamminess of his extremities, together with the tendency to redness and cyanosis of his hands and feet, the nervous tremor when excited, as well as his attacks of angioneurotic edema and other manifestations of this nature, must be considered, as physiological. They are all symptoms which must be attributed directly to the sympathetic nervous system which not only furnishes the nervous mechanism for the regulation of the vasomotor system but also supplies all of the smooth muscle of the gastrointestinal tract and the glandular structures performing the secreting and excreting func-

tions of the body of which the endocrine system is a part. When a sympathetic nervous system acts so abnormally in its visible functions, is it not reasonable to suppose that abnormalities in function exist also in its other activities, such as the maintaining of normal contraction and tone in the gastrointestinal tract, as well as the normal secretions of the stomach, thyroid, suprarenals, ovaries and testicles?

In the clinical manifestations of our nervous patients we are continually observing disturbances of function of this sympathetic neuroglandular mechanism, not only in the vasomotor system but also in all of its other activities. Digestion is often disturbed as is evidenced by the furred tongue, the formation of gas with its accompanying distention and atony, alteration in the menstrual function in the form of dysmenorrhea or amenorrhea, hyperactivity of the thyroid, with persistently increased pulse rate and the asthenic state. Definite and positive disturbances of the character just described are an integral part of the symptoms in nervous cases.

Recently I had an opportunity of observing in a case of vicious vomiting during the early months of pregnancy not only the important rôle which the ovarian function plays in the causation of such symptoms but also the influence of inheritance on this function as well. In this case, in addition to the severe vomiting, there was evidence of what may be called a hypersubjectivity, an abnormal selfconsciousness, insomnia, hysterical symptoms as manifested by alternate laughing and crying, periods of slight mental confusion, with incoherence and increased irritability. The patient's sister told me that both she and her mother had had similar symptoms in the first months of their pregnancies. The vomiting in this case became so severe that an interruption of the pregnancy was found necessary. Inside of three or four days after this had been done, most of the symptoms had passed away.

Another case in point was that of a chorea of pregnancy, chorea gravidarum, also in a young woman, at about the seventh month. In this patient, vicious vomiting had been present during the early months and when the vomiting began to subside the chorea made its appearance. In this patient the jerking movements in her face and body were something frightful to witness. At the time I saw her she was unable either to talk or eat because of them. It was thought best to resort to operative intervention at once, and so a Cæsarean section was performed by the surgeon. In spite of this severe procedure the patient showed a marked improvement inside of three days. In a week's time her choreic movements had disappeared altogether.

Ordinarily we do not have as good an opportunity of observing the influence of the sexual glands in men as we do in women but occasionally cases are encountered which show that their influence here is equally as great.

CASE I.—A young man, aged twenty-one, suffered a severe accident to his testicles, which necessitated their removal. Ten years later, besides the physical changes which, of course, were distinctly feminine in nature, he exhibited a decided love for personal

adornment—perfumes, flowers and fruits. He had spells of easily recognized periodicity, in which he felt unwell, complained of vertigo, exhaustion, headache, increased irritability and mental depression. Outside of these regularly recurring attacks, he was shy and obsessed with different phobias.

As further evidence of the apparently endogenous and idiopathic nature oftentimes of mental states, I will report the following cases:

CASE II.—A patient for many years had suffered from severe attacks of migraine at her menstrual periods which lasted for a day, beginning in the morning and terminating at night. After this patient had passed the menopause, her headaches stopped but seemingly as a transformation of these headaches, regularly, each month, she had one day of severe depression, during which she walked the floor, greatly agitated, sometimes wringing her hands, and was possessed with distressing suicidal impulses.

I recall two cases, both in women, the younger one a niece of the older, who lived in distant parts of the country from each other. Neither one had any knowledge of the nature of the sickness of the other. These patients were both subject to periodical attacks of depression, which seemed to run a definite course and in their attacks were obsessed with the same identical fears.

I relate these cases to show that in any full appreciation of the neuropath and his symptoms, both physical and psychic, his inheritance plays a rôle by no means unimportant and is responsible for both physiological and mental symptoms which are difficult to attribute either to autosuggestion or heterosuggestion or even a pathological suggestibility.

To regard this complicated neuroglandular mechanism as the endogenous and basic factor in all those states grouped under the heading of the psychoneuroses offers, to my mind, the best working hypothesis for a rational explanation of the multitudinous phenomena which such cases exhibit.

We must reflect that the etiological factor may be and usually is a variable one in every case. On the one hand we see cases where the endogenous factors play the chief rôle, not only as in epilepsy and migraine, but also in the neurasthenic and psychic conditions. We also see cases where the physical state, as a result of a severe infection or an exhausting illness, appears to be the chief causative factor, with the endogenous and psychic influence standing in the background. On the other hand, we see cases, and perhaps the majority of them, where the mental element occupies the centre of the stage and the endogenous factors seem relatively unimportant.

In these days when the trend of medical opinion tends to attribute a psychogenetic origin to all nervous phenomena of a functional character, we will be wise if we do not permit ourselves to lose sight of the physical and physiological factors.

There is an old saying which admonishes us to pad the nerves with fat. We have always observed the bad effect of a loss in weight of ten or fifteen pounds in the individual with a nervous diathesis. As he loses his weight, pound by pound, so also he seems to lose his nervous equilibrium and vice versa—as he increases his weight, he ac-

quires nervous stability. Often a very definite relationship may be established between these two things—weight and nervous equilibrium. As a concrete example, I wish to cite the case of a young woman, who, when she weighed one hundred and twenty pounds had a severe attack of migraine once every two weeks and sometimes oftener, but two years later, weighing one hundred and sixty pounds, she rarely had these attacks, sometimes as long an interval as six months occurring between them.

Recently I had a patient, a boy, aged ten, exhibiting typical neurasthenic symptoms, following a slight attack of chorea. In this case, what may be termed the strain, the exciting cause, was insignificant. No mental element was discoverable. The patient had alternating bradycardia and tachycardia, flushing and blanching of the skin of the face and neck, cold extremities, extreme irritability when tired, was easily exhausted and slept poorly. Stories and even pictures of an excitable nature agitated him greatly. The boy was an adopted child and in addition to a bad nervous inheritance, had one testicle which was undescended, and the other was small and atrophic. In this case the endogenous factor seemed to be the chief one, the strain, the physical agent, as represented by the chorea, a minor one, while the influence of the mental state was not perceptible. It seems to me we are justified in recognizing, in such cases as this, what may be termed an endogenous neurasthenia which no doubt is similar in character to those cases which formerly were grouped under the older term of essential neurasthenia.

It is scarcely necessary to call attention to the close relationship existing between the cerebrospinal and the sympathetic nervous systems. We have all experienced ourselves and also been witnesses of this fact many times. In some this relationship seems more delicate, more responsive, more sensitive than in others. In some it is much easier for the state of mind to disturb the normal function of the sympathetic than it is in others, as evidenced by the quickened pulse rate to the least excitement, the dryness of the tongue and mouth when in a state of fear. I think all of us can recall cases of sudden cessation of the menses produced by fright. I can remember three cases of exophthalmic goitre which developed suddenly while the patients were undergoing intense excitement. We have repeatedly seen all sorts of nervous and hysterical symptoms developed in one individual as the result of a sudden shock, while others, in the immediate vicinity, experiencing the same shock, were entirely unaffected. This variation in influence of the cerebrospinal nervous system upon the function of the sympathetic nervous system in different people for the sake of illustration, at least, may be referred to as a difference in contact—what Cannon has termed, a difference in threshold, or, as it were, in the degree of insulation between these two systems. This difference in contact, threshold, insulation, pathological suggestibility—or whatever you may wish to call it—may be regarded as an explanation for the various reactions of different individuals to their own environments. Why, for example, do some, under strain, break down and go to pieces

easily while others remain perfectly unaffected and indifferent through the most trying ordeals.

When one looks over the case records of his nervous patients and asks himself how many of their symptoms would still be left if it were possible to suddenly and completely strip them of all of their fears and change their mental content from that of worry and apprehension to that of hope and contentment, he feels inclined to answer—not many. Granting that it could be done, there is still good reason for thinking that it might be compared to the delousing process of the soldiers who were going back to the trenches the next day. It would soon have to be done all over again. We hear a good deal about the psychological dugouts to which our patients flee in a defensive reaction against their environment but forget to suggest that perhaps these dugouts are similar in nature to the dugouts some one of their forbears have been making use of for generations. While the mental factor in most cases is a very important one and often seems to be the chief one, it is never entirely uncomplicated. The predisposing cause, the inherited and endogenous agencies always have to be reckoned with.

The change in a patient's mental attitude may occur as suddenly and make as great a difference in his general condition as a change in the wind can make in the temperature of Minnesota when it blows from the north or south. The change in the direction of the wind is, of course, directly responsible for the change of temperature—from warm to cold and vice versa, but back of the change in the direction of the wind other forces in atmospheric conditions must be taken into consideration which are in themselves responsible for this change in the wind's direction. So also in the nervous patient, we note the marvelous effect in his symptoms, either for better or worse, apparently depending entirely on the change in his state of mind and so come to the conclusion that the origin of his trouble is wholly psychic, overlooking endogenous disturbances which are in themselves responsible largely for this change, like the atmospheric conditions in their relationship to the wind.

We have spoken frequently of the nervous symptoms of this class of patients. Properly speaking—what are some of these symptoms? I think sometimes there is a tendency to enroll all symptoms for which no satisfactory explanation can be found in this category. The subjective nature of so many of such symptoms is probably responsible for this. It would be difficult to mention all of them, but the following are the symptoms most frequently encountered in nervous cases: Headache, vertigo, restlessness, inability to concentrate, insomnia, loss of ambition, lack of interest in environment, fear and apprehension, hyperirritability, feeling of exhaustion, irritable vasomotor system, gas eructations, abdominal distention and atony, paresthesias, anesthesias, and tremors.

If we carefully investigate the nature of the headaches, for example, of which the neurasthenic complains, we will find that it is no ordinary headache, in fact, strictly speaking, it is not a headache at all in the customary sense in which this term is used. It is a feeling of pressure, a sensation as if the head was in a vise or a steel band was applied around it. If a

neurasthenic patient who complains of his head is closely questioned concerning the nature of these head sensations, it makes no difference whether he lives in St. Paul or Berlin, he will give much the same description of them, thus indicating that the headache of a nervous patient is characteristic in nature. The same thing may be said in regard to all of his other symptoms. They are remarkably similar in the different patients.

To regard these sensations, these so-called subjective symptoms of our nervous patients, as wholly imaginative in character, is only a confession on our part of our lack of a suitable explanation for them. In my opinion, these symptoms are to be regarded as toxic in origin, caused by disturbances in the metabolism of the body as a result of the disturbed functioning of the sympathetic nervous system and the glands which it activates. It is to be remembered that, in so far as the symptoms themselves are concerned, it makes little difference whether this disturbance of function is caused by congenital defects in, or degenerations produced by, disease of the glands or is due to the abnormal stimulation on the part of the sympathetic mechanism, caused by an agitated and disturbed mental state. It would be more appropriate, if instead of speaking of such symptoms as nervous, with only a vague idea of what we mean when we use this term, to speak of them as toxic symptoms of metabolic origin.

In the mental conflict of every neurasthenic and hysterical patient, fear of some kind plays a predominating rôle. It makes little difference so far as the agitation of the patient is concerned whether this fear is real or imaginary in character. If one is awakened in the night by some sound and at once jumps to the conclusion that there is a burglar in his bedroom closet, his fear is going to be just as great as if there actually were one there. If he lies still, afraid to move, his fear increased by every sound which the stillness of the night brings to his overstrained nerves, when morning comes and the daylight shows that his fears were groundless and imaginative, the exhausting effect of the strain he has undergone during the night will be just as real and positive as if a burglar had actually been there. This illustration explains the situation of so many of our nervous patients. Their fears are imaginary but the effect of these fears, because of the disturbances which these fears have caused in the functioning of the sympathetic nervous system, are real and positive. The disturbance in function caused by the cerebrospinal nervous system acting upon the sympathetic system produces changes in the metabolism of the body and these changes in the metabolism create a toxemia which is responsible for the nervous symptoms of which the patient complains.

We see this well illustrated in patients with traumatic neuroses and shell shock. In the cases of traumatic neuroses oftentimes the symptoms do not begin until after the visit of the claim agent or the employment of a lawyer. They are always worse as the date of the trial approaches caused by the increased mental strain and when their cases have finally been ended, either successfully or unsuccessfully, and the thing ceases to disturb their state of

mind, their symptoms disappear. In the shell shock cases the signing of the armistice had the same effect as the termination of litigation has in the cases of traumatic neurosis—the symptoms vanished. The removal of the conditions which were responsible for their disturbed mental state caused the disappearance of their symptoms. These two types of cases have given us a much better understanding of all cases of a similar nature.

To treat such cases intelligently, we should make every effort to ferret out the nature of the strains in the environment of these patients and remove or at least adjust them. We have been too much accustomed to seek for the causes of our patients' complaints in exogenous factors, such as physical defects and focal infections. The idea that these symptoms may be due to some terrible fear, some secret disappointment, some incompatibility in their environment, plus something endogenous and inherited in the patient himself, has not been sufficiently recognized. If we wish to recover lost prestige by our failure in the past with these cases, we must think more broadly concerning them than in terms of infections alone. To endeavor, as is often done, to make infected teeth or tonsils or any other infection as the chief etiological agent in the causation of a neurosis, a psychosis, a migraine, an epilepsy or tic douloureux, shows a woeful misconception of a large and important group of cases. We laugh at the osteopath because he claims a dislocated vertebra pressing on a nerve as the chief cause of his patient's symptomatology. We have equally as much reason for laughter at the medical man who removes tonsils or does a circumcision for the cure of epilepsy, who extracts teeth to cure a tic douloureux, who removes a nasal spur for the relief of migraine or performs a central fixation to cure a neurosis or psychosis.

In order to have the proper conception of the etiology of these cases which are grouped under the general term of psychoneuroses and to which the neuropath belongs, two factors must be carefully considered, the inherited and endogenous on the one hand, as obtained in the family and personal history of the patient and the exciting, on the other, as revealed in the various strains which it is possible to discover in his environment, not forgetting that sometimes the predisposing, sometimes the exciting cause is to be ascribed the predominating rôle. In the light of this conception of the neuropath, what can be done to benefit him? First, we must estimate, as carefully as possible, the weight of his inherited burden, then do our best to seek out the nature of the strains not only physical but also psychic, produced by the fears, the incompatibilities and obstacles which exist in his environment and which are causing his two nervous systems to make contact, to short circuit as it were, and if it is not possible to remove these strains, entirely, endeavor to adjust them so that he will be the better able to endure them.

If we strive to manage our nervous cases in this manner, we will very soon realize as a result of our success that dope and electricity, as well as focal infections, in the treatment of such cases are not the *ultima Thule* and be led to exclaim with Hamlet: "There are more things in heaven and earth, Horatio, than are dreamt of in your philosophy."

IMPAIRMENTS REGARDING FAMILY AND PERSONAL HISTORY.*

Their Expected Mortality.

BY WILLIAM H. E. WEHNER, M. D.,
Philadelphia,

Medical Director of the Fidelity Mutual Life Insurance Company.

Insurance has been defined as "the institution which eliminates risk or which substitutes certainty for uncertainty." (1) It is unquestionably true that "the occurrence of events insured against cannot wholly be prevented" (1), but experience has demonstrated "that the uncertainty of financial loss through such occurrences can be eliminated by distributing the loss over a group" (1). Therefore, "when a large number of people contribute to a common fund from which any individual contributor will receive a certain financial return at the expiration of a given time" (1), or his estate or beneficiary be recompensed financially in case of his premature decease, "the only certain loss sustained will be his personal contribution or the premium charged, and the sum paid to his estate or to his beneficiary is apportioned from the contributions of each member in the group" (1). Hence, it has been well said, "Insurance is the elimination of uncertainty or the replacement of uncertainty by certainty." With morbidity to a great or less degree always near, prudence demands protection to dependents, and affection for those we love insists that such protection be commensurate with present income, in case of accidental or premature death. A protecting power or return of such a nature should not partake of a gamble. When honestly and conservatively conducted modern assurance protection is the safest institution in existence.

Any estimate as to how long a given individual will live is the most uncertain problem known, but a general mortality rate based upon the lives of a great number of individuals can by competent actuarial means be quite accurately determined and a safe, workable forecast of future terminations be as closely ascertained. Babbage states, "Few things are less subject to fluctuation than the duration of life in a multitude of individuals." (2)

The laws of probability indicate that like the law of chance, there must be a law governing mortality. What cause or causes operate in determining that from the dates of birth of a large number of people, a definite number will die each year until all have died, no one knows. Hence, our inability to gauge the actual force of mortality. Notwithstanding this lack of knowledge, however, human ingenuity has, "by studying the records and death rates or rate of death in many groups of individuals and carefully investigating all collateral circumstances" (3) which in the minds of numerous investigators "have probably affected that rate, found it feasible to surround any future group of individuals with what would be approximately the same condition and problems and so anticipate closely the same rate of mortality." (3) To come thus closely to a sound, workable system of estimating the future rate of death of a large group, shows

* Read before the Philadelphia Medical Examiners' Association, February 11, 1920.

the value of accurate mortality statistics, and how, without such excellent tables at hand, certainty would again give way to uncertainty, and a practical accuracy degenerate into primitive chaos.

Accurate and original data in all mortality statistics are of the greatest importance. "The two sources from which the best known mortality tables in existence today have been obtained are, first: Population statistics from census enumerations with mortality records from registration centres and, second, the mortality statistics of insured lives." (4) It is thought to be questionable whether the statistics of a general population can be used in determining the accurate mortality of insured lives. They represent the average death rate of a population group and so approximate the "true law of general mortality," but an insurance company wants to know more particularly as to the mortality occurring among selected lives, for such lives are subject to factors that may influence the death rate considerably, and of necessity have to be carefully considered.

It is true "the mortality tables based on population statistics formed the first scientific basis for insurance rates, but as their approximation to true insurance mortality was not close, they were supplanted by tables based on insured or selected lives as soon as a sufficiently large experience on selected lives was attained. The present tables used by American life insurance companies and required by most state insurance departments as a basis for the valuation of policy liabilities have been built from data of insured lives. Such a mortality table has been described as 'the picture of a generation of individuals passing through time.' (5) Taking a group of persons entering at a certain age, it traces and notes the history of the entire group, year by year, until all have died. The essential features of such a table are the two columns of the number living and the number dying at designated ages. Such is the American experience table which is widely used by the old line companies in the United States, particularly for the computation of premium rates. It is assumed that a group of one hundred thousand persons come under observation at exactly the same moment as they enter the tenth year of life. Of this group 749 die during the year, leaving 99,251 to begin the eleventh year. The table proceeds in this manner to record the number of the original one hundred thousand dying during each year of life and the number living at the beginning of each succeeding year until but three persons of the original group are found to enter upon the ninety-fifth year of life, these three dying during that year. This table represents the mortality data in their final form for use in expressing the probabilities of death and of survival. It is manifestly impossible for any insurance company to insure a group of one hundred thousand persons at exactly the same age and at exactly the same time, and it is equally impossible to keep any such group under observation until all have died. Insurance policies are written at all times of the year and on lives at various ages. It is entirely practicable that a record be kept of all insured lives, showing at each age the number of

persons under observation, and of those observed for one year at least, the number who have died. If data are collected, therefore, showing, first, the ages at which persons come under observation; second, the duration of the period of observation; and third, the number dying during one year for each age, the material will be furnished out of which a mortality table may be constructed. In the United States there is an important classification of tables of three kinds dependent on the data used in their calculation. They are known as select, ultimate and aggregate tables. These terms have reference to the question whether the data used have been affected by medical selection. The tables most used in the United States today by insurance companies are three, i. e., 1, the Actuaries' or Seventeen Offices table was calculated from the experience of seventeen British life insurance companies and was introduced into the United States by Elizar Wright as the standard for the valuation of policies in Massachusetts. This table has at the present time been largely supplemented by, 2, the American Experience table, which was published in 1868 by Sheppard Homans, and was calculated from the mortality experience of the Mutual Life Insurance Company of New York. 3, The National Fraternal Congress table was derived from the experience of two American fraternal orders, and was first published in 1898." (6) Once a satisfactory mortality table has been built, it is but logical sequence to adopt such a table, until a better one has been constructed; and "by applying the laws of probability to it the risk in life insurance is measured and closely approximated." With this rather lengthy résumé as to the foundation upon which all successful life assurance institutions must be built, let us now consider an important part of both the ground and superstructure, medical selection.

The first question presenting itself to the medical director as he scans the pen picture of an applicant seeking insurance protection, is, "Has this man or woman, an average chance of attaining his or her expectancy?" We have seen that the "mean duration of life," or as it is better known in the insurance world, "the expectancy of life," is formulated by the use of an approved mortality table to which is applied the law of average or better, of probability. The expectancy of life, therefore, is not how long an individual may live, but it is or means the average number of years, members of a large group of individuals of the same age will survive.

Medical decision as to the desirability of a risk, must also be influenced by a number of other important factors, the probable working of which on each individual applicant must be quickly and safely determined. Family history, personal history, weight and measurements, occupation, environment, and last, but not least, the habits and character of the person, and the reputation and ability of the medical examiner who has penned the sketch, and the care he has exercised in making the report. These would cover the medical aspects of the case. The issuing of a policy, however, is further dependent upon satisfactory inspection and the favorable scrutinizing views of the authorities who

pass upon financial, business and agency questions.

Let us now see how the family history of an applicant influences medical selection:—An expressed marked longevity in the family history of an applicant, particularly in the parents and grandparents, I believe to be the strongest single factor in estimating the desirability of any risk. The offspring from such a stock, have usually great resisting power. They do not contract infections readily, and if disease is contracted, they resist its ravages longer, respond more readily to treatment, and unless some idiosyncrasy is present, often escape conditions that would be fatal to those not so blessed.

Similarity in build to one's ancestors is also a notably favorable factor, particularly in plus weights. Where an applicant's parents live to the age of seventy, or over, or where their earlier decease resulted from accidental cause or acute disease, especially if advanced age is noted in the grandparents, and the applicant's brothers and sisters appear to be healthy, the family history is assumed to be first class.

The Caucasian race shows the greatest resisting powers as a rule. They certainly show the lowest mortality. The following remarks apply to the white race alone:

Apoplexy in the family history, even two or more cases, if not associated with other impairments, or trivial ones in the applicant, is ordinarily not of serious import. However, with this history a more scrutinizing selection would be made. These applicants show a mortality rate actual to expected of 108 per cent.

Cancer in the family history, two or more cases, is not considered serious. A recent study of a great number of cases has shown that the disease is probably neither hereditary, infectious nor contagious. This class shows a mortality rate actual to expected of 79 per cent.

Epilepsy in the family history is of no moment. Too few could be found. There were 121 instances and two deaths.

Heart disease in the family history, two or more cases, shows a somewhat higher mortality in this class of applicants and would cause a more careful selection to be made. The mortality rate actual to expected is 113 per cent.

Insanity in the family history, two or more cases, is usually of little moment, as affecting the applicant. Mortality of this class is only seventy-four per cent. of the expected.

Pneumonia in the family history, two or more cases, would cause a tighter selection. This is usually not considered an important impairment.

Tuberculosis in the family history profoundly and unfavorably influences the mortality rate of an applicant, particularly if he is a light weight and under thirty five years of age.

An applicant under thirty should be of average weight and even then a history of association with a tuberculous brother or sister or parent, or the fact that a parent died of or has the disease, would occasion a most rigid medical selection. Changing from lower to higher cost plans, as endowments, will not meet the extra mortality

in these cases. Only a lien or rating, imposed on selected cases, will enable the successful handling of this class. Let me state how tuberculosis in an applicant's family history affects the risk. The medico-actuarial mortality investigation developed that the normal death rate from tuberculosis of the lungs for all heights and weights combined is twenty-two and one-half per cent. of the deaths from all causes, at ages of entry under twenty-nine years, and at ages of entry thirty to forty-four years, twelve per cent. With this in mind the following table shows how heavily this disease falls on light weights with a family history of tuberculosis: (7)

VARIATION FROM AVERAGE WEIGHT.

	Entry Age 15-29	Entry Age 30-34
Minus 25 lbs. to minus 45 lbs..	51 per cent.	27 per cent.
Minus 5 lbs. to minus 20 lbs..	48 per cent.	26 per cent.
Average weight to plus 20 lbs..	34 per cent.	12 per cent.
Plus 25 lbs. to plus 45 lbs.....	9 per cent.	3 per cent.

In judging the insurability of risks of this character, we would find a fair average mortality is obtained in subjects having a family history of tuberculosis if we eliminate light weights under thirty years of age. I believe infancy and childhood are preeminently periods when tuberculosis infection is likely to occur, and that danger of infection through the digestive tract is nearly as great as by the respiratory passages.

Clinically, the ages from fourteen to forty-five may be looked upon as a danger zone. At the younger ages at entry with an associated tuberculous family history, selection more particularly rests upon facts as to past and present development, home and occupational environment and habits.

PERSONAL HISTORY

Mortality figures mentioned in any of these impairment classes have been obtained by actual experience of a large number of the old line companies who contributed their individual experiences over a period of twenty-four years and members of the committee in charge thereof were among the most prominent medical directors and actuaries in this country. The material embraced many hundreds of thousands of cases and was furnished for their study by institutions that controlled ninety per cent. of the insurance in force in the United States.

The presence of more than one personal impairment markedly influences any action taken by the medical director, and is frequently the cause of adverse action in many instances. In some prospects, what would appear as an apparently slight impairment would be of marked suggestive import when linked with a defect of presumably little moment. This should always be borne in mind.

Appendicitis—no operation.—One attack within less than two years of date of application shows a mortality of ninety per cent. of the expected. One attack within two to five years from date of application shows a mortality of 103 per cent. of the expected. One attack within five to ten years of date of application shows a mortality of sixty-eight per cent. of the expected. One attack without operation would postpone the case for a full year. Two or more attacks without operation would postpone the case at least three years, but each case

would be judged on its individual merits before final action.

Appendicitis with operation.—If wound is closed at operation—no drainage—we would consider such a case three months after recovery, but would be careful to eliminate any subsequent history of digestive disturbances and obtain full data from the operating surgeon. In a pus case, wound not closed, and drainage used, we would not consider the risk for a year after recovery. Here trouble from adhesions, etc., is feared as it is vastly more likely to occur than in a clean case. In eighty per cent. of drainage cases, however, I think it is safe to assume that if any trouble from adhesions, etc., is to occur, it will occur within one year of operation or not at all.

Asthma.—Great care is used in clearing up such histories and eliminating emphysematous conditions and other causes or effects of an organic nature. Mortality in these cases where one attack has occurred within two years of date of examination is 120 per cent. of the expected. Between two and five years the expected mortality is less. Only the most favorable cases would be accepted and these limited to small amounts and plans going off the books at age of fifty-five or sixty years at the latest. Exceptional cases might be accepted for longer plans if under age of forty provided a lien or rating were imposed. Statistics show that more than one attack within two years of date of application gives a mortality experience of 124 per cent. of the expected, and after two years mortality increases to 129 per cent. of the expected.

Blindness.—Total blindness or eyesight which is poor and progressively growing worse makes a case uninsurable on any plan. Only in exceptional cases of long standing where a constant care taker is employed and unusually favorable environmental conditions present would we insure, and even then only a small amount on a heavy rated endowment plan would be rarely considered. Blindness in one eye, from traumatism where light perception exists and is not growing less, the other eye being sound, would not be a bar to insurance if disability benefits were excluded.

Bladder.—Cystitis of short duration—in young persons is usually of little moment. After forty, however, it may be a manifestation of organic disease. All cases of prostatitis, stone, papilloma, etc., are carefully inquired into, family physician's blank obtained and careful chemical and microscopical examination of one or more specimens made at home office before deciding as to insurability.

Blood spitting.—Is always an impairment of the greatest importance, and may be a symptom of tuberculosis, ulcer of the stomach, or cirrhosis of the liver. Such a history usually postpones for ten years or declines a risk. History of one attack without distinct symptoms of tuberculosis of the lungs occurring less than five years prior to date of application gives a mortality actual to expected of 151 per cent. One attack, five to ten years prior to date of application 131 per cent. and one or more attacks, more than ten years prior to date of application 102 per cent. of the expected. Other factors being favorable such cases may be con-

sidered on selected plans only after that period of time has elapsed.

Change of life.—Unless first class in all other particulars, women at the climacteric should be postponed until the change has been successfully accomplished, particularly if a family or personal neurotic history exists.

Deafness.—If total or marked and increasing the applicant is a poor risk on account of the extra hazard from accident. Deaf mutes if of matured age, however, might be considered, all else being equal, on rated endowment without disability. Partial deafness in one or both ears, if ordinary conversation can be easily heard and a watch's tick recognized when not in contact with the skull, would not ordinarily prevent insurance with disability benefits.

Ear disease.—A history of otitis media or discharge, if recovered from, does not render a case uninsurable. Recurrence or continuation of discharge, if not purulent, offensive and gritty with the absence of evidence of mastoid disease or bony involvement and a sufficiently large perforation in drum, so situated that drainage could take place readily if discharge recurred, would permit of insurance, perhaps with a lien or rating, rarely without. If repeated attacks occur we would obtain an aurist's opinion. Any present ear trouble with persisting discharge would postpone or decline such a case. After a mastoiditis we would insure upon full recovery.

Epilepsy.—Such cases cannot be safely insured on any plan. A history of one or two convulsions in early childhood with no after occurrence is usually of no moment.

Diabetes.—True cases of diabetes mellitus are not insurable on any plan.

Duodenal ulcer.—If diagnosis is unquestionably correct, particularly if confirmed by operative procedure, these cases are insurable two years after full recovery, for moderate amounts on endowment plans, providing no digestive disturbances have occurred since recovery.

Fever.—Typhoid fever cases are taken six months after full recovery. Complete restoration of health and regaining of weight might enable favorable consideration two or three months earlier in rare instances. Cases with history of malaria are postponed until three months after full recovery. An applicant who has had malarial hematuria or lives in a locality where pernicious malarial types abound is ordinarily uninsurable.

Anal fistula.—With or without operation, one attack, less than two years of date of application shows a mortality of 120 per cent. of the expected. One attack within two to five years of application 136 per cent. of the expected and one attack after five years of the date of application 100 per cent. of the expected. If tuberculous cause can be eliminated and successful operation has been done we would insure, unless applicant was a light weight with doubtful family or personal history. In plus weights the history of anal fistula is of comparatively little moment.

Gout.—Under forty it is an exception to receive cases where such a history is confirmed. We would

always investigate carefully and call for all available data. After forty or in any case if we believe true gout to have been present, we would decline to consider. One attack of true gout within five years or less, of date of examination, shows a mortality of 190 per cent. of the expected. One attack of true gout within from five to ten years of date of examination shows a mortality of 172 per cent. of the expected.

Gravel, renal colic, stone in kidney, renal calculus.—One attack with stone passed, negative chemical and microscopical home office specimen and the x ray negative would make such a case insurable after two full years have elapsed. Repeated attacks would decline.

Gonorrhœa.—Postpones a case until full recovery, then we would consider on satisfactory home office specimen and no evidence of sequelæ.

Goitre.—Simple cystic goitre without evidence of pressure and nervous symptoms can be taken on endowment plans for limited amounts. Cases are always carefully selected and full history developed. Any suspicion of an exophthalmic nature or operation for suspected Graves's disease, would render the case uninsurable.

Enlargement of glands.—If not due to tuberculosis, syphilis or other serious disease, glandular enlargements are of little moment. Obtain family physician's blank and eliminate all tuberculosis suspicions before considering. Glandular enlargements of the neck are always looked upon doubtfully and these cases rarely taken.

Disease of gallbladder.—One attack of catarrhal jaundice with family physician's blank showing same to have been unaccompanied with colic or other evidence of cholecystitis and with no subsequent history of digestive disturbances would not prevent insurance. Cases of cholelithiasis (gallstones), however, are not insurable until five years have elapsed since recovery from attack with no digestive disturbances in the interim. Two or more attacks would decline.

Gallstone with operation.—Gallbladder removed or not: Selected cases are insurable for small amounts on endowment plans after two or three years, if no digestive disturbances have been in evidence and other factors are first class.

Gastric ulcer.—Cases with history of true gastric ulcer, whether a gastroenterostomy has been performed or not, are not insurable upon any plan.

Hip disease.—Renders a case uninsurable.

Heart disease.—Valvular disease, myocarditis, cardiac dilatation or hypertrophy render a case uninsurable. A history of valvular disease due to inflammatory rheumatism is particularly of serious import. An irregular or intermittent heart usually postpones or rejects. If cause can be determined—i. e., coffee, tea or tobacco, and is distinctly not of organic nature, we might in a young prospect issue a rated or liened policy. A pulse under fifty-five is frequently of serious import, and a pulse persistently over ninety would be postponed or declined. Only where of long standing in one under forty and where an idiosyncrasy can be satisfactorily established, would the issuing of a modified policy be favorably considered.

Insanity.—In an applicant's history renders a case uninsurable.

Laryngitis.—Cases running an acute course and not of long duration are not of much moment. Long continued cases, chronic forms, however, are frequently due to growths, tuberculosis of chronic thickening of the vocal cords of uncertain cause and are not desirable risks.

Neurasthenia.—The types assumed are legion. Such histories are always carefully investigated and family physician's blanks with full data as to date, symptoms present, duration and treatment obtained. Each case is judged individually and most careful selection made in every instance.

Ovarian disease.—If of functional nature only at menstrual periods, all else being equal, each case is carefully considered individually after obtaining complete data and family physician's blank. Operative procedure in such cases necessitates careful study, attending physician's and surgeon's opinions. Satisfactory findings do not prevent the issuance of endowment policy for small amount with or without a lien or rating.

Paralysis.—If due to central cerebral lesions declines a case. Peripheral forms such as Bell's palsy, wrist drop, scrivener's palsy or the sequelæ of anterior poliomyelitis, if not extreme, render a case insurable on selected plans. Mortality rate in these latter cases is 105 per cent. of the expected.

Pleurisy.—One attack of dry pleurisy of less than ten days' duration we do not hesitate to accept. Cases with effusion are studied carefully and full details with physician's blank obtained. We would hesitate to take a case of serious effusion at any time, particularly in a lightweight or where it is thought a family or probably personal tuberculous factor is present. Cases accompanying pneumonia where good laudable pus has been found and evacuated and recovery has been prompt, would be considered favorably after six months from date of recovery, all else being equal.

Pneumonia.—If fully recovered from, weight regained and no sequelæ present, are insurable after six months.

Prostate gland.—With such a history the risk is declined after forty-five. In young subjects, a physician's statement is secured with complete details and one or more specimens sent to the home office, before decision is given.

Articular rheumatism.—One attack less than two years of date of examination shows a mortality of 120 per cent. of the expected. One attack more than five years since date of examination shows mortality ratio of 109 per cent. of the expected. More than one attack less than two years of date of application, 123 per cent. of the expected. One attack two to five years from date of application 109 per cent. of the expected. Careful selection is always made in these cases and heart critically examined before decision. The muscular forms of rheumatism are usually of no great moment. True rheumatoid arthritis declines such an applicant.

Rupture.—A complete or incomplete hernia, if easily reduced and a properly fitting truss worn would render a case insurable. If no truss is worn a lien or rating would be imposed.

Urethral stricture.—Each case is individually considered as to calibre of the urethra, complications, whether full stream can be easily passed, duration, etc., with chemical and microscopical examination of specimen at head office. Doubtful cases are usually declined. History of esophageal stricture declines.

Syphilis.—Syphilis has the distinction of being an impairment where the remoteness of the original infection adds increasing hazard to the undesirability of the prospect. Under the most favorable conditions the mortality ratio in these cases, whether treated or untreated, remote or recent, is 138 per cent. of the expected. I do not believe any company can afford to absorb even a preferred case of syphilis, even where medical procedure has been followed, no matter how thoroughly, on any life plan at ordinary rates. This particularly applies to the ages of thirty-five and over. At younger ages, other factors being desirable, and if no history of secondary or tertiary symptoms has been discovered, we might, upon satisfactory negative Wassermann blood tests, issue a short rated endowment. These plans must mature not later than fifty or fifty-five years of age, and no disability would be granted.

Tumors.—Such histories are always questionable. Simple cyst or fatty tumors if favorably situated and not extensive do not affect insurability. Epithelioma (notwithstanding its benign nature in many instances), cancer, sarcomata and syphilitic gummata, etc., always decline an applicant.

Vertigo.—Such history unless unquestionably due to digestive indiscretions, refractive troubles of the eye, or idiosyncrasy such as sight of blood, etc., and of immaterial nature, we would not consider insurable. Vertigo is frequently due to organic disease of the brain, serious ear trouble and epilepsy.

Tuberculosis of the lungs.—If tubercle bacilli have ever been demonstrated we would decline no matter how remote the seizure or apparently perfect the cure. Tuberculosis of the glands including scrofulous glands of the neck, one attack less than ten years of date of application gives a mortality actual to expected of 178 per cent. One attack more than ten years of date of application 113 per cent. Tuberculosis of bones, hip, spine and joints, one attack less than ten years of date of application gives a mortality of 190 per cent. of the expected. One attack more than ten years of date of application gives a mortality of 120 per cent. of the expected. Only exceptional cases with such histories might be considered after ten years had elapsed on rated endowment plans.

At the present time I purposely have not referred to a series of important impairments which daily cause anxiety and worry to the medical departments of all insuring companies. I refer to the chemical and microscopical findings of urine, to blood pressure readings and to specific data as to the build of an applicant, i. e., a decided departure from average weight. These impairments would necessitate time and space not contemplated in the scope of this paper and have been reserved for a more op-

portune time. Suffice it to say, each of these factors has a most decided bearing on conservative selection: each must be considered specifically and at the same time weighed as a part of the whole; each must be studied individually and all favorable offsets considered; each must be measured by the medical director's experience tempered by the known actuarial and statistical findings of its class.

THE THERAPEUTIC VALUE OF CUPPING.

Its Use and Abuse.

BY J. EPSTEIN, M. D.,
New York.

In the healing art advantage is taken of every therapeutic means. To cure or alleviate the ills of mankind pharmacotherapy is most frequently used, and when prescribed in the right case and in the right way will always do much good. A lack of knowledge of the science of pharmacology and the art of therapy has created therapeutic pessimists, who timidly use one or two drugs in the treatment of disease, and therapeutic polypharmacists, whose prescriptions are a conglomeration of too many drugs.

In addition to drug therapy, mechanical, thermal, chemical, electrical, psychic and hydrotherapy are occasionally used with good results. The improper or indiscriminate use of any of them does harm to the patient, to the value of the remedy itself and to the physician. One of the most popular mechanical therapeutic agents is dry cupping. This is a remedy of great antiquity and it is used by many people in many lands. It belongs to that group of therapeutic substances known as counterirritants, which, when applied to the surface of the body, will, by their own irritating action, relieve irritation of the underlying deeper structures or organs.

The entire theory on which the physiological action of counterirritation is based is indefinite and uncertain. In the earlier days of medicine, when humoral pathology dominated medical thought, counterirritants were supposed to draw the diseased humors from the deeper organs to the surface of the body. With the advance of medical knowledge the therapeutics of counterirritation and cupping were based on the theory that irritation or suction of the skin produced a local hyperemia, bringing more blood to the surface and thereby relieving congestion of diseased internal organs. It was also thought that surface irritation caused reflex action resulting in favorable circulatory or trophic changes in the underlying organs. The work of Head and

Mackenzie on surface localization in visceral diseases has thrown much light on the subject of counterirritation. According to these observers, every diseased internal organ, through its nerve supply causes an area of hypersensitiveness in a certain segment of the spinal cord. Within this hypersensitive spinal area there are nerves which project to the periphery to supply definite areas or zones of muscle and skin. Through the proximity of certain sensory, visceral and skeletal nerves in the spinal cord, disease or irritation of an internal organ causes an area of pain, tenderness or hypersensitiveness in a corresponding definite area or zone on the surface of the body. It is therefore evident that since visceral irritation affects a definite area on the skin, a counterirritant applied to that surface area will affect the corresponding internal organ.

The humoral theory is mentioned here for historical reasons only. To assume that the therapeutic value of cupping is due to the removal of blood from the internal organs to the surface of the body is erroneous. The entire quantity of blood held in the hyperemic circular spots produced by the cups on any area of the body is insignificant when compared with the quantity of blood which is circulating within the body. To produce sufficient peripheral vasodilatation as to bring more blood to the surface and less to the internal organs quite other therapeutic means are necessary. A warm bath or a mustard bath will cause dilatation of the surface blood vessels and will do more good than any amount of cupping. It is doubtful whether the application of cups, like so many dots, all over the chest will produce reflexly changes in the lungs. To cause reflex action in the lungs nothing will serve the purpose better than the proper application of cold water. A mustard paste, applied all over the chest, especially when the mustard is mixed with warm ground flaxseed, will produce peripheral vasodilatation, and reflexly affect the internal organs.

Whatever the theory on which this popular remedy of cupping is based, its true value as a therapeutic agent can only be determined by practical clinical investigation. During the last two influenza epidemics, when it was hard to find a living human being whose chest had not been cupped either as a prevention or as a cure for influenza or pneumonia, I carefully investigated the therapeutic worth of this old traditional remedy. I have asked quite a number of patients how they felt after being cupped, the cupping usually having been done either on the advice of the family physician or because of their own faith in this inherited household remedy. The majority of patients thought that they were not at all benefited by the cupping. Some said that they felt somewhat better for a while after being cupped but soon felt no change for the better. A few stated that they felt much better after the cupping process and were sure it had saved them from a serious illness. In the cases where the cupping was said to have done much good, it was difficult to tell how much of the benefit was due to the actual cupping and how much to the hypnotic suggestion produced by so old and respected a household remedy. The patients, how-

ever, all complained that the cupping had made them weak and that the skin felt sore and painful.

In addition to their own statements as to their subjective feelings after being cupped, the effect of cupping on the physical signs, the pathological symptoms, and the temperature curve were studied in a number of cases. Observations were made on the possible influence of cupping on the onset, course, and termination of various respiratory diseases.

From this clinical investigation on the subjective and objective effects of cupping it may be definitely stated that it does not prevent or cure influenza or pneumonia or any other disease of the lungs for which it is most commonly used. Cupping may do some good in edema or congestion of the bases of the lungs, in renal congestion, in subacute pleuritis, in lumbago or other muscle aches, in neuritis and neuralgia. Cupping does actual harm to infants, young children, asthenic adults, and the aged. It makes them weak, and their skin sore, painful, and black and blue. The entire process of cupping, with its imposing paraphernalia, is so terrifying to young children that it should never be used in any disease of childhood.

Whatever good there may be in the counterirritation of cupping has been grossly abused. It is being advised in almost any real or imaginary disease of the chest without any diagnostic thought or therapeutic reason. It has become almost the exclusive trade of barbers, discarded nurses, and crafty old women. When cupping is used in the right case with proper care and discretion it may be of some assistance in the care of the sick. That it renders some useful service in the ills of mankind has been attested to by its extensive use as a household remedy for many generations. But its careless, thoughtless, and offhand use for any disease or no disease has done much harm to many patients and brought down this popular remedy to the ranks of a quack medicine and a therapeutic humbug.

222 EAST BROADWAY.

THE BIOCHEMISTRY OF DRUG ADDICTION.

By A. S. HOROVITZ, M. D.,
Cincinnati, Ohio.

The medical profession has always regarded drug addiction as something unethical, to be treated with contempt, probably because it was looked upon as a vice, which they were unable to combat. The contempt for the drug addict became so general that almost every ethical practitioner refused to treat these unfortunate sufferers. National prohibition brought the subject to the foreground and made it a widely discussed topic. Now the public justly looks to the profession for relief and cure.

The helplessness of the profession was not due to the incurability of the drug habit, but rather to a lack of knowledge of the subject. Physiological chemistry and biochemistry had not developed sufficiently to accord investigators a clear picture of the biochemical composition of the protoplasmic struc-

ture of various tissue building cells, either in the normal or in the pathological state.

The wonderful progress made in biochemistry during the last decade has made possible accurate investigations and determination of the qualitative and quantitative makeup of certain chemical complexes, hitherto unknown to science. One type of these chemical complexes is the lipoids. Careful parallel investigations of normal and pathological tissues led to discoveries and conclusions of great value in almost all diseases, including the ailment wrongly designated as drug habit. The name drug habit covers only the inordinate desire for opiates, but does not include the pathological changes which take place in various tissues of the body, especially in the protoplasmic structure of the nervous system. Biochemical investigations prove that the tissues of drug addicts are decidedly poorer in lipoids than those of normal individuals and that the difference in lipoidal content is especially marked in the tissues of the nervous system. The lack of sufficient lipoids in the nervous system is responsible for the longing for drugs, as will be explained later.

Overton and Meyer were among the first to report on the influence of certain lipoids upon poisons and toxins. Their early investigations show that lipoids have a solvent action upon narcotics. Nerking and Reichert state that the introduction of certain lipoids into the blood stream diminishes, or entirely eliminates, the effect of narcotics. Furthermore, it is a well established fact that the lipoids of various organs, as well as of the nervous system, may be extracted and consumed by the administration of narcotic alkaloids. An excess of toxins has a similar effect. The detoxicating action of the lipoids is of considerable significance in cellular physiology. The fact that the detoxicating capacity of lipoids remains after extraction from the mother cell aggregate, gives us another means of controlling certain conditions which previously resisted every effort of the medical profession. One of these is drug addiction.

All narcotic alkaloids have either a stimulating or a paralyzing power, and all have the common characteristic of a solvent action upon the lipoids of the tissues. Through this biochemical activity of the narcotic alkaloids the detoxicating influence is diminished. An abundant quantity of toxins of low nitrogen content in the tissues exert their irritating influence, which requires a certain amount of neutralizing chemicals, in this instance narcotics, usually alkaloids, to overcome the craving produced by the toxins. In this way a gradual progressive destruction takes place in the nerve tissues, requiring more and more opiates for stabilization.

The belief that certain addicts through experience and self-analysis can properly regulate the amount of opiates required daily to keep them balanced, is erroneous and contrary to the pathological findings. It is probable that addicts will regulate the amount of one kind of opiate, but use another. Generally addicts are multinarcotics, using all available drugs.

The rational treatment for restoring the lipoidal equilibrium of the tissues of addicts would be to replace the amount of lipoids lost. The very important fact that the detoxicating power is retained

in their chemical complex when this has been extracted to the same degree as in the mother cell aggregate, supplies us with a reliable foundation on which to base proper therapeutic treatment to overcome the pathological changes caused by narcotics in the tissues, and the craving which is the result of these changes.

Lipoids are found in practically all the various cells of the body of both animals and plants. Their peculiar chemical character makes their use possible. We are in position to determine the synergy of various lipoids, which fact enables us to replace the lost lipoids of the body up to a normal point, bringing the patient into normal condition, both physically and mentally. The clinical and experimental data at hand indicate that the introduction of lipoids into therapeutics will prove a means of enlightening us regarding various aspects of metabolism.

ANALYSIS OF OUTPATIENT MEDICAL WORK.*

A Study of 8,863 Dispensary Records by the Public Health Committee of the New York Academy of Medicine

INTRODUCTION.

In an analysis of the medical work of dispensaries an objective gauge had to be taken as a measure of the efficiency of the different institutions. The only extant and easily analyzable measuring standard is the medical history. Under the prevailing conditions it is admittedly an imperfect standard, but the only one available. This method of study is predicated on the fact that certain basic information concerning the patient's physical condition, past history and environment, as well as results of laboratory and other procedures, must be recorded as an intelligent guide in diagnosis and treatment. It is obviously impossible for anyone to hold in mind the necessary details for a group of persons, particularly in dispensaries where large numbers come to each physician's attention daily and where the medical service is frequently changing and several different physicians may handle the same case. If the records do not contain a minimum of information that is generally recognized as indispensable, it is justifiable to assume that the medical service is of an inadequate character.

The study presented herewith is based on this premise, and is open to the objection that the hurriedly made out records in the dispensaries do not properly represent the work done, and that it is frequently superior to what the records would indicate. Yet, the records constitute the only means by which an objective presentation of medical work can be accomplished, and when a considerable num-

*This constitutes a part of the report on the Dispensary Situation in New York City by the Public Health Committee of the New York Academy of Medicine, of which Dr. Charles L. Dana is chairman, Dr. James Alexander Miller is secretary, and E. H. Lewinski-Corwin, Ph. D., is executive secretary. The membership of the committee is as follows: Dr. John S. Billings, Dr. Nathan E. Brill, Dr. Robert J. Carlisle, Dr. James B. Clemons, Dr. Haven Emerson, Dr. Lewis F. Frissell, Dr. Arpad G. Gerster, Dr. S. S. Goldwater, Dr. John A. Hartwell, Dr. Ward A. Holden, Dr. L. Emmett Holt, Dr. Otto V. Huffman, Dr. Walter B. James, Dr. Walter L. Niles, Dr. Bernard Sachs, Dr. Thomas W. Salmon, Dr. Frederic E. Sondern, Dr. M. Allen Starr, Dr. Howard C. Taylor, Dr. W. Gilman Thompson, Dr. Philip Van Ingen, Dr. Karl M. Vogel, Dr. George B. Wallace, Dr. Cassius H. Watson, Dr. Herbert B. Wilcox.

ber of records is used a fairly accurate picture of the clinical procedures can be obtained. It is to be hoped that this study will stimulate the institutions toward making better provision for the satisfactory recording of medical work in dispensaries.

Three different sets of records have been used in the preparation of this study: First, a large number of sequence cases, or cases filed in the order in which the patients applied to the dispensary, were taken; secondly, an analysis was made of selected diagnosed conditions from the different departments, and thirdly, an analysis was made of records from special institutions. The sequence records were taken from the various departments of the following dispensaries: Bellevue, Beth Israel, Cornell Medical College, Fordham, Gouverneur, Harlem, Lebanon, Lenox Hill, Lincoln, Long Island College, Mount Sinai, New York Hospital, Northeastern, Post-Graduate, Roosevelt, Staten Island, St. Bartholomew's, St. Luke's, St. Mark's, St. Vincent's, Bellevue Medical College, Vanderbilt, West Side.

The reason that selected diagnoses were taken in addition to "sequence" cases, was that cases taken in order of sequence from the general files of the dispensaries and relating to a wide variety of pathological conditions, many of trifling significance, might not adequately reflect the kind and quality of medical service in outpatient departments, and an additional study of selected diagnosed conditions treated for a considerable length of time might in fairness to the institutions well supplement the other study. The conditions chosen were those which readily lend themselves to ambulatory treatment, which run a more or less protracted course, present some medical interest to the physician and which in many instances are the cause of economic and social difficulties to the patients. Accordingly 2,718 such diagnosed records from the several departments were collected and tabulated.

They were taken from twenty-one of the twenty-four dispensaries from which the sequence cases were selected, and from the Presbyterian Hospital, where a filing system arranged by diagnosis had made the collecting of sequence records impossible. At the Staten Island Hospital, the Northeastern Dispensary and St. Bartholomew's Clinic it was not possible to find a sufficient number of diagnosed cases in any of the departments of the institution to make such a study of value for these institutions. At five other institutions—Fordham, Long Island College, Roosevelt, Vanderbilt and Gouverneur—no diagnosed records could be found for the general medical clinic, although they were available in other departments. At Cornell Medical College in the general medical clinic only a few records could be found diagnosed for the selected chronic diseases. At Bellevue and at the Post-Graduate it was necessary to go through the records for eight months to find a sufficient number of cases for purposes of comparison. In departments other than general medical it was not always possible to obtain a sufficient number of records for each group, which accounts for the variety in the numbers taken from different institutions.

A third series of records was taken from the following institutions treating special conditions:

Eye, ear, nose and throat.—Manhattan Eye, Ear, Nose and Throat Hospital; New York Eye and Ear Infirmary; Herman Knapp Memorial Hospital.

Orthopedic.—Hospital for Ruptured and Crippled; Hospital for Deformities and Joint Diseases; New York Orthopedic Hospital.

Neurological.—Neurological Institute.

Dermatological.—New York Skin and Cancer Hospital.

Gynecological.—Woman's Hospital; New York Nursery and Child's Hospital; Lying-In Hospital.

Pediatric.—Babies' Hospital; New York Nursery and Child's Hospital.

In these institutions both sequence and diagnosed records were studied; first, a group of sequence cases was taken, and if this group did not contain a sufficient number of cases of a selected disease to make possible a comparison with the corresponding departments of the general dispensaries, another group was added, but the selection was then limited to diagnosed records of the selected condition. With minor exceptions, all the records were for patients treated from January to April, 1917, and from January to April, 1918, thus providing a basis upon which to judge the effect of the war upon dispensary service and to make the survey represent the average work in two different years.

The number of records of each group of records, sequence, diagnosed, and special institution, is appended herewith.

SEQUENCE RECORDS.

General medical departments.....	1,774
Pediatric departments	398
Neurological departments	247
Surgical departments	946
Dermatological departments	333
Orthopedic departments	140
Gynecological departments	437
Eye, ear, nose, and throat departments.....	695
Total	4,970

RECORDS OF SELECTED DIAGNOSED CASES.

Bronchitis	283
Chronic nephritis	102
Chronic rheumatism	150
Chronic valvular heart lesion.....	219
Rachitis	57

Conjunctivitis	87
Trachoma	25
Otitis media	170
Total	2,716

RECORDS FROM SPECIAL INSTITUTIONS.

Pediatric dispensaries	100
Neurological institute dispensary	140
Skin and cancer hospital dispensary.....	67
Orthopedic dispensaries	322
Gynecological dispensaries	154
Eye, ear, nose, and throat dispensaries.....	394
Total	1,177
Total number of records.....	8,863

The following is a general summary of the findings upon the examinations of the records subdivided under four heads: a, the effect of the war on the quality of dispensary work; b, comparison of special institutions with the corresponding departments of general dispensaries; c, comparison of diagnostic, therapeutic and supervisory procedures for sequence cases by departments and d, comparison of diagnostic procedures for selected diagnosed conditions.

THE EFFECT OF THE WAR ON THE QUALITY OF DISPENSARY WORK.

As noted in the introductory statement, the records studied were taken partly from the files of the first three months of the year 1917 and partly for the same period of the year 1918, in order to make possible a comparison of the dispensary service between these years and to judge to what extent the war had affected ordinary dispensary procedure. The analysis of the records in the general medical, pediatric and neurological departments did not show any definite tendency towards either improvement or deterioration in 1918, compared with the year before. As the results of the comparison for these three departments did not indicate any appreciable change, the comparative study between the work in the prewar and the war periods was not extended to the other departments.

The comparative study in the general medical department showed (Table I) that local examination, laboratory tests, treatment, and revisits were recorded in a slightly higher proportion of cases in 1917 than in 1918. The pediatric departments recorded diagnosis and local examinations to a slightly higher extent in 1917, and in the neurological clinics, the diagnosis, general physical examination, laboratory tests, treatment, and revisits were more often recorded in 1917 than in 1918. The only marked decrease in 1918 was observed in general physical examinations in the neurological departments (52.5 per cent. in 1917; 42.4 per cent. in 1918), and in the

and the pediatric division showed in 1918 an improvement over 1917.

COMPARISON OF SPECIAL INSTITUTIONS WITH THE CORRESPONDING DEPARTMENTS OF GENERAL DISPENSARIES

A comparison of all the cases selected from the special institutions with those from the corresponding departments of the general dispensaries shows that, as a rule, the special institutions are superior in their procedures (Table II). By a juxtaposition of the data as to physical examination, laboratory

frequency of revisits: in 42.4 per cent. of the neurological cases more than one visit was made in 1917 and in only 36.4 per cent. in 1918. For the following items the records were better in 1918: general physical examinations and the noting of diagnoses in the general medical departments; general physical examinations, laboratory tests, treatment and revisits, in the pediatric departments, and local examinations in the neurological clinics. On the whole, the departments of general medicine and of neurology were slightly better in 1917 than in 1918,

responding departments of the general dispensaries excelling the special institution in the record of physical examinations and laboratory tests, but were inferior as to the noting of treatment and revisits. One reason for this is the fact that the special institution under consideration does not treat syphilis in the skin department, and this condition usually calls for more laboratory tests and physical examinations than the other conditions cared for in the dermatological departments. Syphilis, however, was treated in many of the dermatological depart-

ments of the general dispensaries which were compared with the special institution.

When groups of selected cases of a certain disease, obtained from the special departments of the general dispensaries, such as otitis media, conjunctivitis, eczema, malnutrition and lacerated perineum, were compared with similar selected cases from special institutions, the special institutions excelled only in some points and fell below in others (Table III). Laboratory tests were noted more often in the general dispensaries for conjunctivitis, eczema, and lacerated perineum and cervix, and in the special institutions for otitis

found to vary greatly in their procedure, the three departments, general medicine, pediatrics and neurology, treating a large proportion of systemic conditions, constituting one group, and the surgery, gynecology, orthopedics, dermatology, and eye, ear, nose and throat departments, treating more local conditions, falling into another. The former group recorded general physical examination, laboratory tests and revisits in a higher proportion of cases, and the latter local physical examination and diagnosis. As to the recording of treatment no definite classification can be established.

DIAGNOSIS.

Diagnosis was found recorded for a relatively high proportion of cases in all departments, but in a much higher percentage of instances in other departments than in general medicine, where the diagnoses were stated on only 43.9 per cent. of histories. The skin clinics led in this respect, diagnosing 95.5 per cent. of cases; the orthopedic departments were next in order of excellence, with 94.5 per cent., and the ear, nose and throat, with 93.4 per cent. of records diagnosed. From seventy to eighty per cent. of the cases studied were diagnosed in the surgical, neurological, eye and pediatric departments, and 63.4 per cent. of those in the gynecological clinics.

One reason for the low proportion of cases diagnosed in the general medical departments is no doubt the fact that often the conditions referred to this department are obscure and having no definite pathology are difficult to classify. The converse of this explains why the orthopedic and ear, nose and throat departments have diagnoses recorded in such a high percentage of cases. In order to be referred to a special department, a condition must be more or less localized, and consequently of a more definite nature than one treated in the general medical department.

Furthermore, it must be noted that in giving credit for the recording of diagnosis in this survey, anything written on the history form in the space for diagnosis was accepted, irrespective of other considerations. This meant giving no credit in cases where a physical examination recorded on the history made the diagnosis apparent, and accepting

media and malnutrition. The recording of revisits was the only feature in which the special institutions excelled for all the selected conditions compared. In this item, the advantage was very much on the side of the special institutions, which showed revisits for nearly twice as many cases as did the general dispensaries. On the whole, the special institutions were somewhat superior to the corresponding branches of general outpatient clinics.

COMPARISON OF DIAGNOSTIC, THERAPEUTIC AND SUPERVISORY PROCEDURES FOR SEQUENCE CASES BY DEPARTMENTS.

In the analysis of medical work, the most important comparison, of course, is that relating to

TABLE IV.
COMPARISON OF CONTENT OF RECORDS REGARDING DIAGNOSIS, EXAMINATION, LABORATORY TESTS, TREATMENT AND REVISITS, TABULATED BY DEPARTMENTS

Departments	No. of Cases	Diagnosis Recorded		Physical Examination				Laboratory Tests		Treatment Recorded		Patients Making More Than One Visit	
		No.	%	General		Local		No.	%	No.	%	No.	%
		No.	%	No.	%	No.	%	No.	%	No.	%	No.	%

Ear, Nose and Throat	541	505	93.4	3	.5	115	21.2	18	3.3	160	29.6	111	20.5
General Total for all Departments	6309	4291	68.	1248	19.7	1932	30.6	749	11.8	3988	63.1	2028	32.2

the general diagnostic and therapeutic procedures (Table IV). This comparison has been made on the basis of the sequence cases studied in the various departments of the general dispensaries and of special institutions. The several departments have been

comparatively blank record forms containing a single word in the diagnosis space, even when this word was merely a symptom, such as constipation or nervousness. This is one reason why the proportion of cases diagnosed in some of the departments of

the several dispensaries does not always correspond with the proportion of diagnostic procedure indicated.

PHYSICAL EXAMINATION.

The three departments treating the larger proportion of systemic conditions, the general medical, pediatric, and neurological, all recorded a very much higher percentage of general physical examinations than the departments treating conditions which are more local in their nature, but even the former departments indicated general physical examination for less than half of their cases. The proportions of general physical examinations recorded in the different departments are as follows: neurological, 47 per cent.; general medical, 43.5 per cent.; pediatric, 40 per cent.; orthopedic, 11 per cent.; dermatological, 3.7 per cent.; gynecological, 2.9 per cent.; eye, 2.2 per cent.; surgical, 1.6 per cent.; ear, nose and throat, .5 per cent.

When the fact is considered that patients are referred to special departments, as a rule, without any previous physical examination to ascertain whether or not there are present deficiencies other than the one for which special attention is being sought at the time, the very small proportion of general physical examinations noted for the patients in the special departments demonstrates one of the weak points of the present dispensary system.

Local physical examination, as would be expected, was found recorded much more often in the departments treating local conditions than in the other divisions, although the ear, nose and throat and surgical departments exhibited histories less satisfactory in this respect than those from the other special departments. The proportions of local examinations stated in the different departments were as follows: Gynecological, 57.8 per cent.; eye, 49 per cent.; orthopedic, 39.6 per cent.; dermatological, 37 per cent.; pediatric, 28.3 per cent.; surgical, 28.1 per cent.; neurological, 22.6 per cent.; general medical, 22 per cent.; ear, nose and throat, 21.2 per cent.

LABORATORY TESTS.

The three departments treating mainly systemic conditions recorded laboratory tests, including skiagraphs, for a larger proportion of cases than did any other special department except the orthopedic, although histories from all the departments showed the laboratory to have been used for only a small proportion of cases. The percentage of cases recorded as having received laboratory, including röntgenographic, diagnosis from each department was as follows: Orthopedic, 21.2 per cent.; general medical, 19.3 per cent.; neurological, 15.5 per cent.; pediatric, 11.7 per cent.; gynecological, 11 per cent.; surgical, 8.3 per cent.; dermatological, 5 per cent.; ear, nose and throat, 3.3 per cent., and eye, 3.1 per cent. The high score in this procedure in the orthopedic departments was due chiefly to the large proportion of radiographic examinations recorded in these departments.

TREATMENT.

Treatment was recorded for less than three fourths of the patients from every department except general medicine and dermatology, and the line of cleavage between departments caring for systemic disease and those treating local conditions

is not visible here as it is in certain other respects. The treatment accorded the patient was recorded in the following proportions of cases in the different departments: Dermatological, 86.2 per cent.; general medical, 78 per cent.; eye, 74.8 per cent.; orthopedic, 74 per cent.; pediatric, 72.9 per cent.; neurological, 71.9 per cent.; gynecological, 51 per cent.; surgical, 45.6 per cent.; ear, nose and throat, 29.6 per cent.

REVISITS.

As indicated by the recording of revisits, the following departments, all treating a large proportion of chronic cases, excelled in supervision of patients: the pediatric, with this information in 47 per cent. of instances; the dermatological, giving it in 39.7 per cent.; the neurological in 38.1 per cent.; the general medical in 37.5 per cent., and the orthopedic in 31.6 per cent. of cases. The other departments recorded revisits for less than 30 per cent. of cases, in the following proportions: gynecological, 29.8 per cent.; eye, 27.9 per cent.; surgical, 26.7 per cent.; ear, nose and throat, 20.5 per cent. The relative excellence of the pediatric departments in this respect reflects, no doubt, the influence of the class plan of organization as applied to cardiac and malnutrition cases.

GENERAL CONTENT OF RECORDS.

The general content of records, as shown by the average for all departments, is most inadequate. Diagnosis and treatment were recorded for only about two thirds of all patients (68 per cent. and 63.1 per cent., respectively); local examinations and revisits for less than one third (30.6 per cent. and 32.2 per cent.); general physical examination for less than one fifth (19.7 per cent.), and laboratory tests for only about one tenth, or 11.8 per cent. of all patients.

COMPARISON OF DIAGNOSTIC PROCEDURE FOR SELECTED DIAGNOSED CONDITIONS.

Altogether, 2,716 selected diagnosed records were studied, and those refer to bronchitis, chronic nephritis, rheumatism, chronic valvular heart lesions, and gastric ulcer, from the general medical departments; rickets and malnutrition, from the pediatric departments; syphilis of the nervous system and epilepsy, from the neurological departments; fracture and cellulitis, from the surgical departments; eczema, from the dermatological departments; lacerated perineum and gonorrhoea, from the gynecological departments; conjunctivitis, trachoma, and otitis media from the eye, ear, nose and throat departments, and syphilis and gonorrhoea from the genitourinary departments. The tuberculosis cases were omitted from this study because of certain data missing, but a special comparison with the other clinics is given in the special tuberculosis study published in the March, 1920, issue of the *American Review of Tuberculosis*.

Lungs.—Examination of lungs was recorded much more often for the conditions treated in the general medical departments than in any other. It was found recorded for 55.4 per cent. of all cases of bronchitis; 48 per cent. of cases of chronic valvular heart lesions; 46 per cent. of cases of chronic nephritis; 37.3 per cent. of cases of chronic rheu-

matism, and 26.4 per cent. of those of gastric ulcer. The only other disease with a high proportion of lung examinations was rachitis, for which this procedure was noted in 36.8 per cent. of instances.

Heart.—The examination of the heart was recorded for a relatively large proportion of cases for all conditions, and especially for the following diseases treated in the medical departments: chronic heart lesions, 84.9 per cent.; chronic nephritis, 60.7 per cent.; chronic rheumatism, 45.3 per cent.; bronchitis, 38.2 per cent., and gastric ulcer, 25.6 per cent. The only other diseases where examination of the heart was noted in a large proportion of cases were: rachitis, with this item on 38.5 per cent. of the histories studied: syphilis, with it recorded in 12.5 per cent., and syphilis of the nervous system, having it stated in 10.1 per cent. of instances.

Abdomen.—Examination of the abdomen was recorded most often for the diseases treated in the general medical and pediatric departments. This information was given on the following proportions of histories of the conditions stated: gastric ulcer, 58.1 per cent.; heart lesions, 38.8 per cent.; rachitis, 38.5 per cent.; nephritis, 33 per cent.; malnutrition, 34 per cent.; bronchitis, 17.6 per cent.; rheumatism, 16 per cent.

Genitourinary examination.—Genitourinary examination was noted for only six of the diseases studied: 85 per cent. of cases of lacerated perineum; 21.1 per cent. of gonorrhoea patients; 4.1 per cent. of syphilis; 2.4 per cent. of epilepsy; .9 per cent. each of rheumatism and heart lesions.

Muscles and bones.—Examination of muscles and bones was recorded more often for rachitis (in 73.7 per cent. of instances) than for any other condition. This information was noted on the histories of 50.7 per cent. of the fracture cases; 18.6 per cent. of cases of chronic nephritis; 17.3 per cent. of cases of chronic rheumatism, and eleven per cent. of cases of malnutrition.

Skin.—Examination of the skin was recorded for 53.1 per cent. of patients treated for eczema. Case histories of cellulitis and syphilis also had examination of the skin recorded for a large number of cases—in 30.9 per cent. and 23.4 per cent. of instances, respectively.

Nervous system.—The cases of syphilis of the nervous system studied were given an examination of the nervous system in 79.7 per cent. of instances. The other diseases for which such examinations were recorded were: epilepsy, with this procedure stated for 24.3 per cent. of cases; chronic nephritis, with it recorded in 13.7 per cent.; chronic rheumatism, in 12.9 per cent.; syphilis, in 12.5 per cent.; malnutrition in 8.2 per cent., and heart lesions, in 7.7 per cent. of instances.

Special senses.—An examination of the special senses was also recorded for a very high proportion (79.7 per cent.) of cases of syphilis of the nervous system. Such examination was also noted for a large number of cases of conjunctivitis (65.5 per cent.); trachoma (60 per cent.); otitis media (31.1 per cent.) and primary and secondary lues (21.8 per cent.).

Glands.—Examination of glands was recorded for only eight of the diseases studied, and

for a very small proportion of cases of each of these conditions except malnutrition, for which this item was noted on sixteen per cent. of histories.

Teeth.—Teeth were examined for a relatively high proportion of patients treated in the general medical departments and for malnutrition. The cases diagnosed as rheumatism received the most attention in this respect, such examination being recorded in 26 per cent. of instances. It was also reported for 22.5 per cent. of cases of nephritis; for 20 per cent. of cases of malnutrition; for 16 per cent. of heart lesions; 10.6 per cent. of bronchitis, and 6.8 per cent. of cases of gastric ulcer studied.

Throat.—Examination of the throat was recorded about as often as was examination of the teeth, but for twice as many cases of malnutrition as of chronic rheumatism. The conditions receiving the largest proportions of throat examinations were: malnutrition, 20 per cent.; nephritis, 18.6 per cent.; chronic heart lesions, 16.6 per cent.; bronchitis, 14.4 per cent.; rheumatism, 10 per cent.; otitis media, 8.2 per cent.; rachitis, 7 per cent., and syphilis, 6.7 per cent.

Tongue.—The condition of the tongue was noted most often for the disease treated in the general medical and neurological departments. This information was noted for chronic nephritis in 7.8 per cent. of instances; for syphilis of the nervous system in 7.2 per cent.; for heart lesions in 5.5 per cent.; for bronchitis in 5.3 per cent.; for epilepsy in 4.8 per cent., and for malnutrition in 4.7 per cent. of cases.

Temperature.—Temperature was recorded for a larger number of cases of malnutrition (27.6 per cent.) than of any other condition. This item was also recorded on the histories of heart lesions in 26.4 per cent. of instances; for chronic nephritis in 20.5 per cent.; for bronchitis in 16.6 per cent.; for rachitis in 15.8 per cent. and for rheumatism in 14 per cent. of instances.

Pulse.—Pulse was noted for cases of heart lesion in a larger proportion of instances (35.6 per cent.) than for any other disease. This item was recorded, however, for 19.7 per cent. of cases of nephritis; for 14 per cent. of cases of rheumatism; for 8.6 per cent. of cases of malnutrition, and for 7.7 per cent. of those of bronchitis.

Respiration.—Respiration was noted for only six of the various conditions studied; 23.5 per cent. of cases of chronic nephritis; 22 per cent. of chronic valvular heart lesion; 4.9 per cent. of bronchitis; 3.8 per cent. of malnutrition; 2.6 per cent. of chronic rheumatism, and .4 per cent. of eczema.

Weight.—Weight was recorded for only seven of the different conditions studied, as follows: 16 per cent. of cases of malnutrition; 12.7 per cent. of nephritis; 8.9 per cent. of rheumatism; 7.7 per cent. of heart lesions; 5.1 per cent. of gastric ulcer; 3.8 per cent. of bronchitis, and .5 per cent. of syphilis. The instance last noted was the only case where weight has found recorded outside of the general medical and pediatric departments.

Blood pressure.—Blood pressure was never found recorded, except in the general medical and pediatric departments, and for only a small percentage of

the diseases treated in these departments, with the exception of nephritis, for which this procedure was noted in 17.8 per cent. of instances; rheumatism, for which it was stated for 7.3 per cent. and heart lesions, for 5 per cent. of instances.

General physical examination.—By far the more adequate general physical examinations were recorded in the general medical, pediatric, and neurological departments, which, as has been emphasized heretofore, treat conditions systemic in nature. Very little physical examination was noted on the histories from the surgical departments, or for gonorrhoea, whether treated in gynecological or genitourinary departments. The eye, ear, nose and throat departments also had little record of physical examination, except of the special senses. Of all the items of physical examination stated for the various diseases studied, examination of the heart was recorded for the largest proportion, 20.8 per cent. of all the cases. The lungs, also, were examined in a relatively high proportion of all cases, 18.3 per cent.; the abdomen in 12.6 per cent., the skin in 10.7 per cent., and the special senses in 10.4 per cent. of instances. All other divisions of physical examination were recorded for less than 10 per cent. of cases: temperature; pulse; examination of teeth, throat, genitourinary tract, muscles and bones, nervous system, all for between five and ten per cent. of patients whose histories were analyzed; while examinations of tongue, glands, weight, blood pressure and respiration were recorded for less than four per cent. of cases.

Of all the conditions studied gonorrhoea, as indicated by the records, would seem to have been given the least of general physical examination, as on 77.5 per cent. of case histories of this condition, examination was not noted. Likewise, 68.8 per cent. of cases of otitis media, 68.1 per cent. of cellulitis, 58.5 per cent. of epilepsy; 49.2 per cent. of fracture, 48.4 per cent. of syphilis, 46 per cent. of eczema and 40 per cent. of trachoma had no physical examination recorded. The diseases accorded the highest proportions of physical examinations were: syphilis of the nervous system, for which some examination was recorded for all but 10.1 per cent. of cases; heart lesions, for which this item was noted for all but 11.4 per cent., and lacerated perineum, all but 14.6 per cent. of which were examined.

LABORATORY TESTS.

Uranalysis.—In accordance with natural expectation, the analysis of urine for sugar and albumin was recorded for a higher proportion of cases of chronic nephritis than of any other condition and that was in only 39.2 per cent. of the cases. This procedure was noted for 12.8 per cent. of cases of heart lesions; for gastric ulcer in 11.1 per cent.; for rheumatism in 9.7 per cent. and for epilepsy in 4.9 per cent. of instances. Microscopic uranalysis was recorded more often for gonorrhoea than for chronic nephritis, this item being noted in 44.9 per cent. of cases for the former and 37.2 per cent. for the latter condition. The other diseases having this procedure noted in a relatively high proportion of cases were, heart lesions, 10.5 per cent.; rheumatism, 10.4 per cent.; gastric ulcer, 6 per cent., and epilepsy, 4.9 per cent.

Skiagraphic examination.—An x ray examination was recorded on some proportion of the histories of all diseases studied except eczema, conjunctivitis and trachoma; and for a relatively higher proportion in cases of fracture (56.7 per cent.) and of gastric ulcer (45.3 per cent.) than in others. The patients with chronic nephritis had röntgenographic examination recorded in 7.8 per cent. of instances; those with rheumatism in 6 per cent.; those with rachitis in 5.3 per cent.; and those with other conditions all in proportions less than 5 per cent.

Wassermann test.—Although the Wassermann test was noted for a slightly higher proportion of cases than was the x ray examination, the application of the former was more restricted, as four conditions (fracture, cellulitis, conjunctivitis, and trachoma) had no record of this procedure. As would be expected, syphilis and syphilis of the nervous system received this examination most often—in 67.2 per cent. and 78.2 per cent. of cases respectively. The only other condition having this item noted for more than the average number of cases was epilepsy, with the Wassermann test recorded for 12.2 per cent. of cases.

Blood examination.—A blood count or hemoglobin test was noted much more often for cases of gastric ulcer, being recorded in 11.1 per cent. of instances, than for any other condition. Blood examination was entered on the histories of 3.6 per cent. of cases of malnutrition, and in nephritis for 2.9 per cent., in heart lesions for 1.8 per cent., in syphilis of the nervous system for 1.4 per cent.; and in syphilis, rheumatism and bronchitis, each for less than one per cent. of the cases studied.

Analysis of sputum.—Analysis of sputum was recorded for only six of the conditions studied, as follows: for bronchitis in 7.8 per cent. of cases; for gastric ulcer in 3.4 per cent.; for nephritis in 2 per cent.; for heart lesions and malnutrition, each in 1.8 per cent., and for rheumatism in .7 per cent.

Other laboratory tests.—A Von Pirquet test was recorded for 8.6 per cent. of cases of malnutrition, 1.8 per cent. of heart lesions, .8 per cent. of eczema and .3 per cent. of bronchitis. Smear was noted for 34 per cent. of the patients with gonorrhoea; 2.3 per cent. of those with heart lesions; 1.9 per cent. of those with lacerated perineum; 1.1 per cent. with conjunctivitis, and .5 per cent. with syphilis. A complement fixation test was recorded for 4.8 per cent. of cases of epilepsy, .7 per cent. of rheumatism and .5 per cent. of eczema. Spinal puncture was noted on the case histories of only three conditions—21.7 per cent. of the cases of syphilis of the nervous system; 5.1 per cent. of cases of gonorrhoea, and 1.6 per cent. of syphilis. Stools were examined for blood in only one case of gastric ulcer. A test meal was noted on the records of but two conditions: for 37.6 per cent. of the cases of gastric ulcer and for .9 per cent. of patients with heart lesions.

GENERAL COMPARISON

Laboratory tests were recorded as having been employed much more often for the diseases treated in the general medical departments than for those from the other clinics. Of all the laboratory tests for the conditions discussed, x ray examination and the Wassermann test were stated to have been used

for the highest proportion of cases, 9.5 per cent. and 9.6 per cent. respectively. Microscopic uranalysis was noted for 6.6 per cent. of cases; analysis of urine for sugar and albumin for 5 per cent.; smear for 2.3 per cent.; and test meal, examination of stools, hemoglobin and blood count, sputum, Von Pirquet, complement fixation tests and spinal puncture investigations for only small proportions of cases (less than two per cent.).

The diseases for which the highest proportions of laboratory tests were recorded were: syphilis of the nervous system, which had this procedure noted in some form for 84 per cent. of cases; syphilis, with tests recorded in 67.2 per cent. of instances; nephritis and gonorrhoea, with this information on 66.7 per cent. of case histories for each; gastric ulcer in 59 per cent., and fracture in 56.7 per cent. of instances. No laboratory tests whatever were recorded for the cases of trachoma studied; 98.8 per cent. of the cases of conjunctivitis; 96.5 per cent. of cases of otitis media; 98.2 per cent. of cases of cellulitis; 95.4 per cent. of cases of eczema, and 93.2 per cent. of rachitis, received no laboratory tests.

The highest proportion of any laboratory test for a given condition was 78.2 per cent. of Wassermann reaction for syphilis of the nervous system. The following conditions all received laboratory tests in a high proportion of cases: syphilis, 67.2 per cent. of Wassermann; fracture, 56.7 per cent., and gastric ulcer, 45.3 per cent. of x ray; gonorrhoea, 44.9 per cent. of microscopic uranalysis; nephritis, 39.2 per cent. of uranalysis for sugar and albumin and 37.2 per cent. of microscopic uranalysis; gastric ulcer, 37.6 per cent. of test meals and gonorrhoea, thirty-four per cent. of smears.

CONCLUSION.

The foregoing analysis speaks for itself. The dispensaries and out patient departments of hospitals evidently do not utilize sufficiently their opportunities for the application of accurate methods in diagnosis and treatment. An improvement in these respects and in the general adaptation of the dispensaries to the functions they are intended to fulfill is much to be desired in the interests of both medical advancement and public health.

LONDON LETTER.

(From our own correspondent)

British Association for the Advancement of Science.

LONDON, September 4, 1920.

On August 24, 1920, the eighty-eighth annual meeting of the British Association for the Advancement of Science opened at Cardiff, Wales, and was well attended by British men of science and oversea visitors. The president for the year is Professor W. A. Herdman, professor of oceanography in the University of Liverpool. The association was founded at York in 1831 as a result of the efforts of Sir David Brewster and can point to a great past, when men like Humphrey Davy, Herschel, Playfair, Hurley, Lyndall, Kelvin, Clark Maxwell, Abel, Vernon Harcourt, Murchison, and a host of others were the shining lights in the sci-

entific firmament. The association generally deals with questions of medical interest, and the meeting this year is no exception to the rule.

Professor Karl Pearson, in his presidential address before the Section of Anthropology, impressed upon his audience that anthropology must be pursued on broader lines if it were to yield more useful results to mankind. He confessed that perhaps he was a scientific heretic in that he did not believe in science for its own sake but for man's sake. What, he asked were anthropologists doing during the war with their own science? The whole period of the war produced the most difficult problems in folk psychology. There were occasions innumerable when thousands of lives and heavy expenditure of money might have been saved by a greater knowledge of what creates and what discourages folk movements in the various races of the world. India, Egypt, Ireland, even our present relations with Italy and America, showed only too painfully how difficult we found it to appreciate the psychology of other nations. We would not surmount these difficulties until anthropologists took a wider view of the material they had to record. It was not the physical measurement of native races which was a fundamental feature of anthropometry today; it was the psychometry and vigorimetry of white as well as of dark skinned men that must become the main subject of study. Anthropology should be made a wise counsellor of the state, a counsellor in political, commercial, and social matters. "I will not," said Professor Pearson, "go so far as to say that if the science of man had been developed to the extent of physical science in all European countries, and had then had its due authority recognized, there would have been no war, but I will venture to say that the war would have been of a different character and we should not have felt that the fate of European society and European culture hung in the balance, as at this moment they certainly do."

The man of today is precisely what his past history and his prehistory have made him. It is impossible to build your man for the future until you have studied the origin of his physical and mental constitution. Whence did he draw his good and evil characteristics? Are they the product of his nature or his nurture? Man has not a plastic mind and body which the enthusiastic reformer can at will mold to the model of his golden age ideals. He has taken thousands of years to grow into what he is, and only by like processes of evolution, intensified and speeded up, if we work consciously and with full knowledge of the past, can we build his future. It does matter in regard to the gravest problems before mankind today whether our ancestry was hylobatic or troglodyte. If the spirit of violence be innate in man, if there be times when he not only sees red but rejoices in it, and that was the strong impression I formed when I crossed Germany on August 1, 1914, then outbreaks of violence will not cease till troglodyte mentality is bred out of man. That is why the question of troglodyte or hylobatic ancestry is not a pursuit of dead bones. It is a vital problem on which turns much of folk psychology. It is a problem utile to the state."

or express money order, payable to A. R. Elliott Publishing Co.,
or by registered mail, as the publishers are not responsible for
money sent by unregistered mail. Remittances from Foreign Coun-
tries should be made with International Money Orders.

Entered at the Post Office at New York and admitted for transpor-
tation through the mail as second class matter.

NEW YORK, SATURDAY, OCTOBER 16, 1920.

DISORDERLY ACTION OF THE HEART.

During the war disorderly action of the heart was greatly in evidence and the condition was closely studied. Much useful knowledge on the subject has been accumulated which should be and no doubt will be of much service in medical practice, as it must be borne in mind that this symptom complex is by no means confined to those who have served in the army. Dr. W. I. Ritchie read a paper on prognosis in certain affections of the heart before the Medico-Chirurgical Society of Edinburgh on July 7, 1920, published in the *Lancet* on September 25th, in which he refers at some length to disorderly action of the heart. He pointed out that when the man who was always a weakling, unfit to play games at school, and who found the true level in a quiet, sedentary, unambitious walk of life, attempts to undertake larger responsibilities, he becomes incapacitated by the giddiness, fatigue, palpitation, precordial pain, and other symptoms characterizing this disorder. This type of person will never become robust, but those in whom the disorder has arisen as a sequel to shell concussion, or in civil life to some other form of trauma, may be expected to improve slowly under judicious treatment.

After excluding this group of cases, and those in whom is found viscerotoposis, obesity, arterio-sclerosis, early pulmonary tuberculosis and hyperthyroidism, Ritchie states that in over forty per cent. of these patients there is evidence of some

recent infection, and in an additional ten per cent. there is anemia, presumably of toxic origin. In all these cases, fifty per cent. of the total, the prognosis, in Ritchie's opinion, is good. In fact it is not the heart that is primarily at fault. Therefore do not give a guarded prognosis and coddle the patient. A good prognosis is the first essential in restoring the patient's confidence. He should be told that there is little the matter with him, not be allowed to remain in bed, nor waited upon more than is absolutely necessary.

At first massage and passive exercise are of value and when he has begun to walk he should be encouraged to undertake an increasing amount of physical exercise daily. He should soon be taking active exercise out of doors. Drugs are seldom indicated and digitalis is wholly useless. In the army this mode of treatment was remarkably successful. However, in civil life the prospects of good recovery are not so uniformly good. The patient does not lead such a healthy life as does a soldier; he is less amenable to control. Physical training under skilled supervision is costly, and not so efficient as in the army; there are devoted relatives whose influence is the reverse of helpful, and in certain grades of the community there is the sure expectation that incapacity for work will be compensated by grants from public funds. Yet, with all these drawbacks, Ritchie assures us that brilliant results may be obtained, and a man or woman who has been practically bedridden for months may, within a few weeks, be leading an active and useful life. It is also instructive to learn that the cases in which the dominant manifestations are those of neurasthenia are the most intractable and the most prone to relapse.

The diagnosis of heart disease, or rather the differential diagnosis of organic and functional heart disease, is a matter concerning which the general practitioner often knows little. Gross lesions he is able to detect, but the more subtle forms of heart disorder he is likely to pass by or to magnify greatly. This inability to diagnose correctly was shown over and over again during the war when men were labelled as having heart disease, who on examination by really experienced physicians were found to be practically sound in this respect.

To Sir James Mackenzie is chiefly due the honor of demonstrating how to diagnose affections of the heart and how to treat them. There is no doubt that Ritchie is right in recommending that a good prognosis should be given in these cases and that the patient should take

regulated physical exercise. Sane and rational ways of treating heart disorders have happily come into vogue based, of course, on correct diagnosis. It is obvious that in order that correct diagnosis may be arrived at the medical student and practitioner must be well trained in modern methods of diagnosis and treatment.

PHYSICIAN-AUTHORS: JOSIAH GILBERT HOLLAND

The medical profession is not always a royal road to wealth. This is not an exciting bit of news. A number of physicians have, from time to time, had more than a suspicion of the fact. In sooth, there have been authentic instances where physicians have considered it necessary to abandon the profession to keep body and soul together—an extreme measure that reflects only on the resourcefulness of the physician. There is the case of Dr. Josiah Gilbert Holland. Whether it was youthful impatience, or injudicious location, or some other reason, is not known, but Dr. Holland became discouraged after about two years' practice and returned to other pursuits. He had studied four years at the Berkshire Medical College, at Pittsfield, Mass., receiving his degree in 1844, and entered practice at Springfield, Mass.

Holland did not immediately return to editorial work and literature, in which field he became a best seller. He spent a few months as a country school teacher and traveling daguerreotypist and got his first taste of journalism as publisher of the *Bay State Weekly Courier*. The *Courier* failed in a few months and he went to Richmond, Va., to teach school. He seemed to have been fairly well launched on a career as an educator, for his next position was as superintendent of the public schools of Vicksburg, Miss., but in 1849 he got an opportunity to join the staff of the Springfield, Mass., *Republican*, and accepted it. His writings, mostly under the pseudonym of Timothy Titcomb, were largely responsible for putting the *Republican* in the front rank of American newspapers. In time he became part owner of the *Republican* and in 1866 sold his interest for fourteen times as much as he had paid for it. He then took a long vacation in Europe and it was there he planned a new monthly magazine, originally known as *Scribner's Monthly* from which has grown the *Century Magazine* of today. Holland was the editor of the magazine from its establishment until his death.

As a writer Holland was preeminently a moralist. With him literary work never was a matter of art for art's sake. His was the rôle of uplifter. Because of this lack of literary finish his work

was freely criticized. Reviewers fell upon him mercilessly, but that fact did not deter the less fastidious public from buying his books by the hundreds of thousands. Perhaps the most popular of his prose was the novel *Seven Oaks* and his most popular verse the long narrative poem, *Bitter Sweet*, which James Russell Lowell called "an obstinately charming little book." "We mean it as very high praise," said Lowell, "when we say that *Bitter Sweet* is one of the few books that have found the secret of drawing up and assimilating the juices of this New World of ours." *Kathrina*, another of Holland's long poems, was a close rival of Longfellow's *Hiawatha* in its day. Today it is almost unknown.

It was Holland's poetry that drew most of the fire of the critics. The *New York Sun* had dubbed him "the American Tupper," for like Tupper (Martin Farquahar Tupper, an English writer who was at the time an object of great derision) he did much commonplace moralizing. The Tupper designation clung to him the rest of his life and hurt him deeply. Edward Eggleston, author of *The Hoosier Schoolmaster*, described Dr. Holland as a man of dignified and impressive presence, "a man of rare simplicity who loved approbation and craved affection." To such a man the undisguised sneers of the reviewers were gall in his cup of happiness over large sales. But though the judgment of the critics was against his writings, there was none that failed to recognize the charm of his personality and Richard Watson Gilder and Edmund Clarence Stedman, among others, felt the loss of him so keenly that they inscribed poems to his memory.

Besides *Bitter Sweet* and *Kathrina*, Dr. Holland's poetry also included *Garnered Sheaves*, a collection of shorter poems; and *The Puritan's Guest* and *The Mistress of the Manse*, lengthy poems of early New England life. His novels, in addition to *Seven Oaks*, included *Miss Gilbert's Career*, *Nicholas Minturn*, *Arthur Bonnicastle* and *The Bay Path* all of which had New England settings and all of which were greatly popular. His novels were undoubtedly his best work, artistically considered. He also published several books of shorter prose writings, the inspirational nature of which may be judged from their titles—*Letters to the Young*, *Gold Foil*, *Plain Talks on Family Subjects* and others. He also wrote *The Life of Abraham Lincoln*, of which nearly 200,000 copies were sold. Holland also was a popular lecturer on social topics and took an active part in the civic life of New York. In 1872 he was appointed a member of the city board of education and later became president of the board. He also was chairman of the board of trustees of New York University. He died suddenly in New York

on October 12, 1881, at the age of sixty-two, having been born on July 24, 1819, at Belchertown, Mass. Death came as he was busy writing an editorial on poverty as a means of developing character. The editorial, half finished, was based on the lives of Presidents Lincoln and Garfield. The latter, a personal friend of Holland, had just died as the result of wounds inflicted by the assassin Guiteau.

TORSION OF THE SPERMATIC CORD.

Among the clinical lesions of the testicle resulting from morbid changes in its vasculonervous pedicle torsion of the cord is paramount. In order that the testicle can twist on the cord the gland must plunge in the vaginalis as the heart does in the pericardium, that is to say, an embryonal defect exists having as a consequence the absence of the mesorchium, the testicle being suspended like a cherry on its stem. In these circumstances a strain or violent movement will cause torsion of the pedicle with the resulting clinical phenomena. Vanverts was able to collect only forty-four reported cases to which he added one of his own and after clinical and experimental researches on the subject he came to two conclusions different from those of his predecessors which relate to the evolution and surgical treatment of the lesions. According to the opinion of most observers, torsion of the cord almost invariably results in suppuration and septic gangrene of the structures involved. Now Vanverts maintains that these phenomena only occur when there is a superadded infection and the aseptic focus that the testicle represents after its own circulation has been cut off should not be any more exposed to infection than would be a subcutaneous hematoma. For this reason Vanverts believed that recovery with simple atrophy of the testicle without suppuration is the rule both in man and animals.

The experiments undertaken to demonstrate this special viewpoint were positive and conclusive in this respect, so that Vanverts has been led to regard the testicle as being much less compromised in its vitality after torsion of the cord than is generally admitted unless an infection becomes superadded. Too much importance must not be attributed to the vascular lesions. Some observers—Volkman, Miflet, Neumann, and English—have recorded curious instances of hemorrhagic gangrene of the testicle without torsion of the cord including them either among cases of torsion of the testicle or among those of primary phlebitis or arteritis of the vessels of the cord. In fact torsion and phlebitis often coexist as in Bevan's case of gangrene of the testicle in which the phlebitis of the spermatic veins of an ectopic testicle was most manifest. The venous coagulum being filled with

bacteria, while torsion of the cord was distinctly made out. In Nicoladom's case the veins were completely occluded and the artery partially so. This was likewise the condition found by Keers and Langlet in their cases.

Unquestionably, the effects of torsion vary according to the presence or absence of blood infection and comparatively with Chauveau's researches, it may be admitted that in many if blood infection does not preexist or follow, torsion ends in simple atrophy of the testicle. Although not denying the frequency of phlebitis and venous and arterial thromboses following torsion there is reason to ask whether or not among these cases some were not in reality simple primary phlebitis and venous and arterial thromboses with a torsion more apparent than real and Scheeds has remarked that torsion of the testicle may merely be a secondary symptom and not the cause of necrobiosis of the testicle which often takes place spontaneously. But if we consider only simple cases it appears evident that when no infection exists the morbid changes arising in the testicle can only be attributed to some mechanical factor. If torsion causes a complete occlusion of the elements of the cord the surgeon in some cases provokes the same condition of affairs with no untoward results to the testicle.

Lucas-Championniere excised the cord in eight cases of operation for large inguinal hernia and eight cases of operation for large inguinal hernia and the operation in no way affected the testicle although the gland was deprived of its excretory duct and arterial supply. The gland at first swelled and was painful but the tumefaction soon retrogressed and never completely atrophied. Carlier is also of the opinion that an aseptic total excision of the cord does not necessarily result in necrosis of the testicle and absence of atrophy may, in some cases, be attributed to anastomoses of the arteries of the cord with the arterial circulation of the bursæ.

These results conflict with the findings in atrophy of the testicle sometimes occurring rapidly after operations for varicocele in young adults or in cases of hernia where the spermatic artery has been divided unintentionally. This may be due to absence or insufficiency of the collateral circulation in youth—as in the case of dogs—hence the necessity of maintaining a more complete arterial irrigation of the testicle in young people than those of advanced years. The age of the patient, the individual differences in the blood supply and the length of time the patient is followed after operation must all be taken into consideration. When this is done sufficiently numerous and careful histological examinations will then have some real value.

BASAL PNEUMONIC RESIDUES IN CHILDREN.

It is a well known fact that after children have been suffering from pneumococcal infections of the lungs they fail to recover completely, and also measles, whooping cough, influenza, especially in mouth breathers, and in rickety, badly nourished children, frequently leave a bronchopneumonic condition which may be overlooked. In *Tubercle*, September last, Dr. Walker Overend urges a more frequent radiological examination of the chest in children who have undergone attacks of any of these infections. He points out that many of the physical signs simulate those of tuberculosis, and that if there should be a clear family history of tuberculosis, the diagnosis of phthisis may be hastily made by the medical attendant or by the school medical officer, and the child sent to the tuberculosis dispensary for further observation or for sanatorium treatment.

It is shown that Sutherland and Jubb examined the sputum of 230 children under suspicion of tuberculosis during the period April, 1911, to October, 1912; they found only nine per cent. were positive. In the sputum of these children the pneumococcus constituted the most abundant organism. According to Overend the following statements seem justifiable: 1. Many cases of illhealth after pneumonia and infectious disease among children are due to unresolved pneumonia produced by a chronic pneumococcal infection, and are not tuberculous. 2. Bronchiectasis of the internal moiety of the lower lobe, or of the whole lobe, is more likely to follow attacks of chronic or indurative basal pneumonia; disseminated patches of bronchopneumonia are more likely to produce areas of diffuse bronchial dilatation. 3. After removal of enlarged tonsils and adenoids, the expediency of surgical intervention should again be discussed if the lower lobe alone is solid, honey-combed with bronchiectasis abscesses and dilated bronchi, and also accompanied by symptoms of septic absorption.

JACOB'S LADDER.

The harassed municipal surgeon must sometimes wish an exact account of Jacob's ladder had been given, for he has to contend with accidents brought about by faultily constructed ones which, breaking, twisting, slipping, falling, hurl a workman to destruction. Then follow the loss of time or life to the worker, surgical assistance, sick allowance or pension, witnessing in the courts, and all this procedure brought about by faulty ladders or, very often, by thoughtless or daring men. People who view lofty buildings under construction little know that so great is the risk run by workers that Rule 1222 of the Industrial Commission says that none but skilled workmen who thoroughly understand the

dangers shall build the scaffolding whose faulty construction may lead to accidents on ladders, etc. Another worry coming to the municipal surgeon is the "contributory negligence" one. The men will slide down levels, jump from higher levels, even consider the ladders installed as a reflection on their agility, or say they breed habits of carelessness. Distinct specifications are made for the making of ladders, but, we fear, faults creep in even as in airplane building. To reduce the 1,000 accidents which occur almost yearly would be encouraging because they do not include many scaffolding accidents.

DISCARNATE SPIRITS.

In these days, when every morning there are paragraphs concerning those who have slipped out of the back door of Life by means of knife and rope, gas fumes, poison, it may be consoling to relatives who are burdened not only with grief but shame, to learn from the spiritists that there are not only good spirits, but weak ones, hovering around, working us evil, though well meaning. These discarnate spirits believe it is sad sometimes that human souls must tarry in this world when everything is against them. They long to have them enjoy the larger, freer life. If one of these spirits becomes attuned to a weak or diseased mind, it may suggest suicide, but purely from a desire to help. Suicides are generally deemed irresponsible. This theory confirms it; but one reluctantly admits the invading of our borderland by weak minded spirits. Devils and angels we know, but how are we to discern these others?

News Items.

International Congress Against Alcoholism.—The fifteenth International Congress against Alcoholism was held in Washington, D. C., September 21st to 26th.

Anniversary of Ether Day.—The seventy-fourth anniversary of Ether Day will be observed with suitable exercises at the Massachusetts General Hospital, on Monday, October 18th. The address will be delivered by Dr. Alonzo E. Taylor, of the University of Pennsylvania.

Insanitary Jails.—The New York City Police Department plans to abandon many of the jails in the police stations as the conditions have been shown to be insanitary and inadequate. Many improvements are contemplated and it is thought that \$500,000 will be required to make the necessary changes.

Aged Count a Ship's Surgeon.—Count Eugene Gerard Fraysses is the surgeon on the Fabre liner *Asia*. He is seventy years old and a veteran of the Franco-Prussian war of 1870. He also served in the recent war and has received many decorations, including that of commander of the Legion of Honor.

A Tuberculosis Preventorium in Grand Rapids, Mich.—The tuberculosis preventorium established by the Antituberculosis Society of Grand Rapids, Mich., was thrown open for inspection on September 19th. It has accommodation for twenty-five patients.

Yellow Fever in Mexico.—Yellow fever is reported to be spreading in Mexico. A press dispatch quotes official statements to the effect that there are 100 cases in Vera Cruz and between thirty-five and fifty in Tampico and that the epidemic has spread to other cities.

Vacancies in the Social Hygiene Board.—The United States Civil Service Commission announces examinations for several vacancies in the United States Interdepartmental Social Hygiene Board, for duty in Washington, D. C., and in the field. For full particulars regarding these examinations address the Commission, Washington, D. C.

Poliomyelitis Commission in Massachusetts.—A commission has been appointed at Harvard University to investigate the outbreak of poliomyelitis in Massachusetts, consisting of Dr. Milton J. Rosenau, professor of preventive medicine, Dr. Robert W. Lovett, professor of orthopedic surgery, and Dr. Francis W. Peabody, professor of medicine.

Mental Clinic for Children.—A free mental clinic for children was opened at St. Joseph's Hospital, New York, on Wednesday afternoon, October 13th. This clinic is equipped to examine and advise both in cases of mental disease and mental defect, and is under the direction of a psychiatrist from the Hudson River State Hospital, assisted by a psychometric examiner from the State Commission for Mental Defectives.

China Medical Missionaries Meet.—The following officers were elected by the China Medical Missionary Association at its annual meeting in Peking in February, 1920: President, Dr. C. F. Johnson, of Tsinan; vice-president, Dr. Thomas Gillison, of Tsinan; executive secretary, Dr. R. C. Beebe, of Shanghai; recording secretary, Dr. H. H. Morris, of Shanghai; editor of *China Medical Journal*, Dr. E. M. Merrins, of Shanghai.

Antinoise Campaign.—Dr. Royal S. Copeland, Health Commissioner of the City of New York, from a study of the existing conditions has been convinced that certain classes of industry should be prevented from encroaching upon residential sections in order that the residents be protected from the noise which they produce. Hucksters, rattling automobiles and the clatter of dishes in restaurants tend to increase the din. In this way the health of the community is affected.

Personal.—Dr. Fred H. Albee, of New York, was the guest of the Chicago Medical Society at a banquet given at the University Club on Wednesday, October 6th. Later Dr. Albee delivered a lecture on Osteoplastic Surgery, which was illustrated with lantern slides.

Dr. J. Lewis Amster has been appointed consulting surgeon of the penitentiary and correctional hospitals of New York City.

Smallpox on Ocean Liner.—The Holland-American liner *Nieuw Amsterdam*, which arrived in New York on October 12th, from Rotterdam, with 621 cabin and 1,673 steerage passengers, was detained in quarantine by the Health Officer of the Port on account of a case of smallpox in the steerage. The *Nieuw Amsterdam* will be detained at quarantine indefinitely with the 1,673 steerage passengers on board.

Gives American Hospital to Italy.—A children's hospital has been offered to Italy by the Committee on the American Tribute to Italy. It will be called the International Child Welfare at Rome.

British Surgeon Brings Gift.—Sir Berkeley Moynihan, who recently left England to attend the convention of the American College of Surgeons in Montreal, brings with him the silver mace which is the gift of the consulting surgeons of the British army and is a memento of the assistance they received from American colleagues during the war.

Red Cross Medical Personnel in Europe.—The Red Cross medical report for July, 1920, shows ninety-six physicians, nine dentists, ten pharmacists and one laboratory man, making a total of 116 medical personnel in Europe. This number, however, has been cut rapidly by the expiration of contracts so that there are now only about fifty medical men still in Red Cross service in Europe.

Serum Treatment of Appendicitis.—According to press dispatches, Professor Pierre Delbet, of the University of Paris, announces the successful treatment of appendicitis by an antigangrenous serum, instead of by operation. Professor Delbet is reported to have said that the tests have extended over a period of thirteen years and the results have been satisfactory.

University of Paris.—A diploma of radiology and radiotherapy has been instituted by the medical faculty of the University of Paris. M. Gosset, professor of external pathology, has been named for the chair of the surgical clinic to replace M. Quénu, retired. M. Vaquez, professor of internal pathology, has been named for the chair of the therapeutic clinic in place of M. Robin, retired.

A Typhus Hospital in Poland.—At the request of the League of Red Cross Societies a large hospital for research work in typhus fever will be operated in connection with the American Red Cross Hospital at Wilno. For the last two years hospitals in northern and eastern Poland have been overcrowded with typhus fever patients, and in localities where the hospital service was inadequate whole communities have been wiped out.

Red Cross Society Establishes a Health Service.—The American Red Cross Society announces the establishment of a department of health service and an extension of its nursing service. The organization has 36,000 nurses on its rolls working in more than 15,000 communities. In order to increase the number of qualified public health nurses 288 scholarships have been established and 67 loans have been made from the national fund, and in addition approximately 250 scholarships have been awarded by the various chapters.

Public Lectures on the League of Red Cross Societies and the League of Nations.—Professor F. F. Roget, of the University of Geneva, will deliver three public lectures in London on October 18th, 25th, and 29th. The first lecture will be on the League of Nations and the League of Red Cross Societies, the second the declaration of the five national delegations sitting in conference at Cannes will be considered, and the third will deal with the program of work laid down for the medical department of the League of Red Cross Societies.

Leprosy Committee in Philippines.—Dr. Vicente de Jesus, acting director of health of the Philippines, has appointed a Leprosy Investigation Committee to meet at Manila from time to time for the purpose of undertaking investigations in connection with the treatment of leprosy. The committee consists of Dr. José P. Bantug, Philippine Health Service, chairman; Dr. H. W. Wade, University of the Philippines, pathologist and Bureau of Science; Dr. Liborio Gomez, Bureau of Science, bacteriologist; Dr. Daniel de la Paz, University of the Philippines, pharmacologist; Dr. Granville A. Perkins, Bureau of Science, chemist; Dr. Proceso Gabriel, Philippine Health Service, and Dr. Luis Guerrero, University of the Philippines, clinicians.

American Scientists to Explore Amazon Basin.—A party of American scientists, headed by Dr. H. H. Rusby, dean of the College of Pharmacy, Columbia University, are planning an expedition to South America early next year for the purpose of studying medicinal plants, insects and animals, with the hope that discoveries of economic value may be made. Search will be made for supplies of certain drugs now in use and for others not now known to science, and several new drugs will be investigated. About one thousand miles of the Amazon Basin in Eastern Ecuador and Peru will be explored. The expedition is to be financed by the H. K. Mulford Company, of Philadelphia, and is called the Mulford Biological Exploration of the Amazon.

Tuberculosis Conferences.—The North Atlantic Tuberculosis Conference held its seventh annual meeting in Richmond, Va., last week, with delegates in attendance from eight states. Dr. Thomas J. Riley, general secretary of the Bureau of Charities, Brooklyn, presided at one of the sessions and presented a paper dealing with the service in Brooklyn on behalf not only of tuberculosis victims but also of crippled children and the blind. Dr. Louis I. Harris, of the New York health department, was also present and presented a paper on Tuberculosis as an Industrial Problem.

The Southern Tuberculosis Conference met in Jacksonville, Fla., October 11th to 13th, with state health officers from Mississippi, Georgia, Kentucky, and Florida in attendance.

Meetings of Local Medical Societies.—The following local medical societies will meet during the coming week:

Monday, October 18th.—New York Academy of Medicine (Section in Ophthalmology); Medical Association of the Greater City of New York; Psychiatric Society of Ward's Island; Yorkville Medical Society.

Tuesday, October 19th.—New York Academy of Medicine (Section in Medicine); Federation of Medical Economic Leagues of New York.

Wednesday, October 20th.—New York Academy of Medicine (Section in Genitourinary Diseases); Geriatric Society; Medicolegal Society; Northwestern Medical and Surgical Society; Alumni Association of the City Hospital.

Thursday, October 21st.—New York Academy of Medicine (stated meeting); New York Celtic Medical Society.

Friday, October 22d.—Academy of Pathological Science; Audubon Medical Society; New York Clinical Society; Society of Alumni of Sloane Hospital for Women; Brooklyn Society of Internal Medicine.

Saturday, October 23d.—Lenox Medical and Surgical Society; New York Medical and Surgical Society; West End Medical Society.

First Aid on Pullmans.—The Pullman car service is giving the American Red Cross first aid training to the entire force of colored maids employed on the transcontinental trains. Several of the women have already finished the course and now carry as part of their equipment the regulation first aid kit. The Pullman Company has arranged with the New York County chapter of the Red Cross to give the course of training in first aid and home hygiene to some hundreds of maids reporting to its New York terminal.

Indiana State Medical Association.—The annual meeting of this society was held in South Bend, September 23d to 25th, under the presidency of Dr. Charles H. McCully, of Logansport. The following officers were elected: President, Dr. David Ross, of Indianapolis; first vice-president, Dr. Hugh J. White, of Hammond; second vice-president, Dr. Ira M. Washburn, of Rensselaer; third vice-president, Dr. Otto R. Spigler, of Terre Haute; secretary-treasurer, Dr. Charles N. Combs, of Terre Haute (reelected). The next annual meeting will be held in Indianapolis, September 27 to 29, 1921.

Died.

BIGELOW.—In Island Falls, Me., on Sunday, September 26th, Dr. Frederick F. Bigelow, aged sixty-two years.

CARROLL.—In Brooklyn, N. Y., on Saturday, October 2nd, Dr. Edward J. Carroll.

CLARK.—In Staten Island, N. Y., on Tuesday, October 5th, Dr. Frederick E. Clark, aged seventy-three years.

CLAY.—In Malta, Mont., on Sunday, September 5th, Dr. George W. Clay, aged forty-seven years.

CONNORS.—In Boston, Mass., on Tuesday, October 5th, Dr. Willett Spurgeon Connors, aged fifty-one years.

D'AQUIN.—In New Orleans, La., on Wednesday, September 8th, Dr. John Joseph d'Aquin, aged forty-eight years.

DUPEE.—In Bridgeport, Conn., on Wednesday, September 29th, Dr. Edward Wilson Dupee, aged forty-eight years.

ELLINWOOD.—In Rome, N. Y., on Friday, October 1st, Dr. Eliza Maria Ellinwood, aged seventy-one years.

GIBBONS.—In Stockton, Cal., on Tuesday, September 21st, Dr. William Edward Gibbons, aged seventy-five years.

GRAHAM.—In Little Falls, N. Y., on Saturday, September 25th, aged thirty-six years.

HARRIS.—In Atlantic City, N. J., on Wednesday, October 6th, Dr. Robert Edward Harris, aged thirty-nine years.

HICKS.—In Menominee, Mich., on Sunday, September 26th, Dr. Walter Raleigh Hicks, aged fifty-five years.

HOWELL.—In Cogan Station, Pa., on Tuesday, October 5th, Dr. William M. Howell, aged seventy-three years.

HUHNER.—In New Orleans, La., on Friday, September 10th, Dr. George Huhner, aged seventy-one years.

LARKEY.—In Oakland, Cal., on Sunday, September 26th, Dr. Alonzo S. Larkey.

MAXSON.—In Berkeley, Cal., on Sunday, September 26th, Dr. Harriet S. Maxson, aged fifty-one years.

MCDONALD.—In Coblenz, Germany, on Wednesday, October 6th, Dr. James Wilson McDonald, of Fairmount, W. Va., aged fifty-nine years.

ROTHWELL.—In Denver, Col., on Tuesday, September 7th, Dr. Edwin J. Rothwell, aged seventy-eight years.

ROWE.—In Boston, Mas., on Saturday, September 18th, Dr. Anna Forrest Rowe, of Brooklyn, aged sixty-three years.

Book Reviews

NEW BOOKS ON THE TUBERCULOSIS PROBLEM.

The Shibboleths of Tuberculosis. By MARCUS PATERSON, M. D.; Medical Superintendent, Metropolitan Asylums Board, Colindale Hospital; Late Medical Superintendent, Brompton Hospital Sanatorium, Frimley; Medical Director, King Edward VII Welsh National Memorial Association; Resident Medical Officer, Brompton Hospital, London. New York: E. P. Dutton and Company, 1920. Pp. ii-239.

A Study on the Epidemiology of Tuberculosis. With Special Reference to Tuberculosis of the Tropics and of the Negro Race. By GEORGE E. BUSHNELL, Ph.D., M. D., Colonel, United States Army, Medical Corps, retired, Honorary Vice-President and Director of the National Tuberculosis Association of the United States. Illustrated. New York: William Wood and Company, 1920. Pp. v-221.

The reviewer remembers an English doctor bringing charts and views of Frimley Sanatorium to Johns Hopkins Medical Society and giving an address on that which was novel and giving good results in the treatment. He was very convincing and many were convinced.

Only the enthusiastic, the really dutiful, will be grateful to Dr. Marcus Paterson of Frimley for airing and making a clean sweep of erroneous statements, false doctrines of which his work there and elsewhere has taught him the pervasion and evil. He finds about fifty-nine, so imagine the nuisance and mess he creates pulling them down, but he does not believe in patching up or compromising because these statements were once believed in by great men in medicine and are still believed by the laity.

To give the first shibboleth will show that the others are clear and well put. It is, Why sterilize milk and neglect butter and cheese? These also could be purchasable. The English and American Public Health service have both demonstrated tubercle bacilli in cheese two months old and in butter ninety-nine days old.

Then, having reviewed the fifty-nine, he says what he has found:

That open air treatment and homes for tuberculosis are not sanatoria. A "little gardening" is neither graduated labor nor autoinoculation, which latter is a natural method of treatment, and inoculation tests of sputum and blood should always be made when microscopic examinations yield negative results. Practically all cases of pleurisy or hemoptysis are due to tuberculosis. That it is better to test by exercise. That climate, if not actually unsuitable, has little to do with treatment. That our treatment of those carrying sputum flasks is unreasonable: a man with one is a safer neighbor than one who uses his handkerchief. Also that patients may have bacilli free sputum.

Finally, Nageli has shown that large numbers have recovered from tuberculosis without their being aware they had it. This is an indication of an increasing high natural resistance to the disease, and a proper appreciation of autoinoculation would be of infinite value to the state. Too much attention is given to the value of physical signs at rest, disregarding tests by graded exercise.

He draws a good picture of the (English)

apathy. Confronted with an undeniable fact that tuberculosis is preventable, he supposes a Great Britain practically free, then allowing a weekly shipload of one thousand, or, practically, fifty-two thousand, which is about the annual mortality, to land there. Every step necessary to see that it did not take root would be made as rapidly as if fighting an Asiatic plague.

He makes some remarks on the qualifications of a medical superintendent of a sanatorium. "The patience of Job and a capacity for working twelve hours a day, seven days a week." Walther, of Nordrach, touched the bedrock of successful treatment when he said it was not the buildings of the sanatorium, but the man in charge. The idea of any open air place where patients do as they like and are overfed being called a sanatorium is absurd. The patients generally become fat, neurotic and selfish.

The book is so lucid and instructive that it deserves more space than can be given. It gives much food for reflection—reflection that must lead to determined action against the enemy.

The reviewer came across an epitaph on the grave of a Dr. Moses Little (1766-1811). The whole family died of tuberculosis, but Dr. Marcus Paterson would most probably say ignorance.

"Phthisis insatiabilis

Patrem, matremque devorasti

Parce! O parce liberis."

but the children died shortly after their parents.

* * *

There is a certain amount of usefulness in carefully retelling and explaining what everyone knows, because there never was a greater fallacy than that everyone does know. But when to common information is added some carefully trimmed ideas which tell of great consideration of the subject, the small audience who took back seats that they might more easily escape, will be reinforced and give good attention. The man on the platform says that to understand tuberculosis of the temperate zone and of our race, we must know also how it affects other races, but the epidemiological data are little known and are often in inaccessible periodicals. He undertakes to tell us all about them and therein lies the attraction of his book. He has on his mind the great prevailing ignorance of the disease as it affects races as yet not fully tuberculized, and wants to help doctors who meet the disease in far away countries, though he admits the difficulty of getting facts and will not condescend to use airy statements however impressive. He thinks the von Pirquet test will become increasingly important, not only in the tropics but also at home, and recommends the wider study of tuberculosis, not only in large cities but in such places as Samoa and Porto Rico, where the date of introduction is comparatively recent.

Dr. Bushnell pursues the enemy all over the world asking, When did it come? How did it come? He divides the countries into two classes and finds the law of Römer holds good: That where it is a rare disease the cases are acute and fatal: Where common, it is chronic and, relatively, benign. That is,

contact affords a certain protection. This was proved by the fine work of von Pirquet and others working with the tuberculin reaction, who proved that, in European cities at least, the adult population was thoroughly tuberculized. We comprehend this in reading of such races as the Marquesas (South Seas) about whom Buisson says that the population will soon disappear. The tribe of Hapaa is said to have numbered 400; first smallpox reduced them by one fourth, then tuberculosis exterminated them save two. The natives of Tierra del Fuego once numbered 5,000; of these, barely 300 remained in 1910. The natives say that, before the whites came, people only died of old age.

As a note of cheerfulness in this mortuarial information, we are told that tuberculization sets in—that is, unless all are exterminated, when it would be superfluous! Instances of this are American Samoa, Tahiti and Hawaii. One class in all communities, the children, are always exposed to primary tuberculosis, and the urgency of a determined fight by undermining ignorance and securing sanitation is inestimable.

The chapter on the American negro and the American Indian is full of interest, also the one on Epidemics of Tuberculosis and Prophylaxis of the Nonimmunized. It would be difficult to comment fully on the book. For to do so would mean a larger quotation than space allows. The author does not claim original investigation, but he may rightly claim originality in putting old facts in a new light.

DIAGNOSIS OF CANCER

The Exact Diagnosis of Latent Cancer. An Inquiry Into the True Significance of the Morphological Changes in the Blood. By O. C. GRUNER, M. D. Philadelphia: P. Blakiston's Son & Co., 1919. Pp. v-79.

In this small monograph Dr. Gruner is careful to state that from a study of the blood alone it is not possible to secure an accurate diagnosis. However, he considers it possible to attain a fairly accurate diagnosis of latent cancer when the various data possible to secure are correlated and the proper deductions made. The essential thing to do, as he points out, is to establish the relationship between the various hemic phenomena and the underlying biological processes. He seeks primarily to establish a new concept of the interpretation of the various clinical findings. From the blood picture he shows us many deductions can be made. The drop of blood is a true sample of all the blood in the body and we are told it should serve as an index of great value. It is of interest to note that while Gruner attaches much importance to the hematology of a patient he tells us to investigate carefully the background of the patient, his home life, his business surroundings, so that we may be able to eliminate, or give full value to the functional disorders or the malfunctioning of any of the ductless glands which may have their origin in some psychic disorder.

This warning is a very healthy note in a monograph which dwells upon minuteness in diagnosis. If we can study the little things without allowing them to master us, we will be taking a long step forward in diagnostic medicine. To be sure, can-

cer is one of the most baffling diseases known to medicine and the method of approach adopted by Gruner should go far toward helping us grasp the fundamental underlying causes of this dread disease.

X RAY ATLAS

The X Ray Atlas of the Systemic Arteries of the Body. By H. C. ORRIN, O. B. E., F. R. C. S., Ed. Fellow of Royal Society of Medicine, London; Civil Surgeon Attached Third London General Hospital, R. A. M. C. (T.). Illustrated. New York: William Wood & Co., 1920. Pp. i-91.

This series of remarkable x ray plates illustrating the anatomy of the vascular system has appeared in *The Archives of Radiology*. Work of this character should lead to a revision of our study of the blood vessels, for the subject presented in this fashion gives a new concept of the arteriovenous system of the human body. A visual projection of the vascular system is made possible, especially by the use of the stereoscopic plates. New values are gained. The anastomotic and distributory elements of this vast network which reaches every cell in the body attains a new significance. We should not be led into the fallacy of allowing these x ray studies to supplant careful anatomical studies by dissection and cross section; they should rather be used as supplemental to the other studies.

The arrangement followed by Orrin is the head and neck, including the arch of the aorta, the upper extremity, the thorax, the abdomen, the pelvis and lower extremity. The work has been done with painstaking care and the result is a series of beautiful photographs. The book should be received with favor by anatomists, and surgeons in every branch of the profession.

SURGEON GENERAL STERNBERG.

A Biography of George Miller Sternberg. By His Wife, MARTHA L. STERNBERG. Illustrated. Chicago: American Medical Association, 1920. Pp. ix-331.

The best biography is one which retains its interest after many years and beguiles into reading it those who never knew the man, for none can write comprehendingly without giving the life of the times his hero lived in, and so the book becomes an interesting reference volume.

The task which lay before the author was to depict fairly a triple personality—her husband as doctor, scientist and soldier—and this has been successfully done. The fourth page finds him assistant surgeon in the U. S. Army, dodging bullets at Bull Run; then follow his work as army surgeon at many out of the way places, disease fighting being varied with natural history studies and exciting discoveries in shell mounds and ancient burial places. He could not choose his dwelling place, and it was often in an unsanitary place or where disease flourished because tolerated by ignorance or indifference. The chapter on the Nez Perces Campaign delightfully savors of Fenimore Cooper, and the reader half regrets Sternberg's transportation from Walla-Walla to the Havana Yellow Fever Commission. We who enjoy the fruits of such work can hardly imagine the hopes defeated, the toil in the laboratory, the distasteful task of refuting theories advanced by confrères, which Sternberg went through. He was certainly the pioneer bacteriologist in America. His

discovery of the pneumococcus before Pasteur is well known, and he most assuredly cleared the ground for Walter Reed's discovery. But where he cleared he also encouraged valiant scientists to walk. In his ten years as surgeon general he realized his ideal of establishing a laboratory at every military post in the country and created the Army Medical School. The Army Nurse Corps was also of his making; also the Dental Corps. Best of all, he fought that arch enemy, tuberculosis, and established a hospital at Fort Bayard and many general hospitals during the Spanish-American war, which war was begun with the usual skirmishing for obviously needed men and supplies with reactionaries at Washington, officials who could not see the economy of having medical officers fully trained in hospital war work.

One rather regrets that neat, cold tombstone at the end of the life. It has an air of finality; its very weight seems to press out any vital spark of heavenly flame; whereas George Sternberg is still living, working, in the men who desire, as he did, a happy victory over all disease.

SELFHEALTH AS A HABIT.

Selfhealth as a Habit. By EUSTACE MILES, M. A., Formerly Scholar of King's College, and Honors Coach and Lecturer at Cambridge University; Assistant Master at Rugby School; Amateur Champion at Racquets and Tennis; Author of *How to Prepare Essays*, *How to Remember*, etc. Illustrated. New York: E. P. Dutton & Co., 1919; London and Toronto: J. M. Dent & Sons, Ltd. Pp. v-341.

Some twenty years ago, right in the heart of London a new restaurant appeared. No chops or steaks or meat foods of any kind, just vegetables, cereals, fruits. The young, the faddy, the dyspeptic cautiously ventured in and looked suspiciously at the dishes offered. It was generally expected that the usual notice "This Shop to Let" would soon appear. Eustace Miles and his wife walked around among the tables with explanations vocal and printed and gently enticed people to learn a little of the insides into which they were putting the food. Last year, when on a visit to London, I found the shop still open and no new undertaking business opened nearby. Certainly the advice in this, Eustace Miles's last book, on how to eat less ought to be feverishly read in these H. C. L. days.

What is this selfhealth? A state of satisfactory well being, independent of particular surroundings. It radiates health to others. It means selfmastery, increasing intelligence. Frequently repeated deep and full breathing, simple exercises, water sipping, the avoidance of worry, the cultivation of happiness will all help. Read the chapters on Economy and Rest, Position and Expression, Better Breathing, Balanced Diets, Exercise, Hobbies, Mainly About Helping Others. Every suggestion is good and will not make one faddy or abnormally self-conscious. No expense is involved, rather less for the ordinary person, but Mr. Miles imagines a co-operation from restaurateurs, landlords, and employers which does not exist. His dietary plan, when well carried out and unstinted, is capital. But send the homeless man to a pure food restaurant and he comes away not half satisfied. With a meat

order, however small, he gets five cents knocked off soup, roll and butter for nothing, and at least one vegetable. Possibly tea or coffee is five cents cheaper also. Now at the pure food place, soup is fifteen cents, bread and butter are charged for, salad—one wilted lettuce leaf and two slices of tomato—is ten or fifteen cents, one tablespoonful of any vegetable or fruit is priced the same, and a dish—eggs, macaroni, curry—from the menu is twenty-five to forty cents, and they are so digestible that he is hungry again three hours later, not being able to afford enough.

Then life in a rooming house—the stuffy bedroom, his sitting room the streets or parks, no inclination to exercise after a ride on crowded car or a long day's work, the daily bath with a queue at the rooming house waiting to get in, the sipping of water with none save that down three flights of stairs, and a smudgy jam glass to drink from. I am not depreciating the author's advice, but simply putting in a plea for those seemingly obstinate people who do not follow his advice. The book is very reasonable and holds nothing to make a man a fidgety nuisance or to behave as though he was the only one to possess a stomach.

OSCAR WILDE.

A Critic in Pall Mall. By OSCAR WILDE. Reviews and Miscellanies. New York: G. P. Putnam's Sons. Pp. vi-290.

To judge fairly of an author's book it should first be judged as a book and the impression it creates without also judging the author. Then, in extenuation of faults, his life, education, peculiar circumstances should be weighed and his condemnation pronounced only when he has wilfully and plainly, not given his best, or when he has treated his readers discourteously by giving them ill-dressed untruths in an attempt to be witty.

Taking then this little book without regard to its author: "The reviewer unconsciously gave not only the hour he could have spared, but another two, which proved pleasant reading. Among the best of the reviews is Aristotle at Afternoon Tea and Some Literary Ladies. Yates, Swinburne and Henley come in for some rather severe criticism. Of Swinburne it has been said he was a master of language, rather, language was his master. Words dominated him, alliteration tyrannizes over him." There are some amusing accounts of Mr. Rawnsley trying to get intimate details of Wordsworth from the farm folk in Westmoreland. "He wrote poetry because he couldn't help it. He was not a man as folks could crack wi', nor not a man as could crack wi' folks."

Wilde has high praise for William Morris's translation of the *Odyssey* and for Walter Pater's *Appreciations*, which he says is "an exquisite collection of exquisite essays, of delicately wrought works of art." The *Sententiae* at the end of the book are wholesome without hurting, as good sarcasm should be.

Satire should, like polished razor keen,
Wound with a touch that's neither felt nor seen.

And the book is worth being accorded a companionship in our life because the author has given of his best and it is good.

Miscellany from Home and Foreign Journals

Nondiphtheritic Pseudomembranous Laryngitis.—R. Rendue (*Lyon médical*, March 25, 1920) reports the case of a man aged thirty-two years admitted to a hospital for what appeared to be an ordinary laryngotracheal bronchitis, with slight fever, some hoarseness, cough, and a few rhonchi and sibilant sounds. Two weeks later the patient had improved, but was still hoarse. Laryngoscopy showed a creamy, white false membrane on the anterior valves of the vocal cords, contrasting by its color with the swollen posterior valves. There was slight enlargement of the glands below the angle of the jaw. Swabbing of the cords showed that the material was actually pseudomembrane and not merely white adherent mucus. No Klebs-Loeffler bacilli could be found, but staphylococci were present. This patient never exhibited dyspnea nor signs of pseudomembranous bronchitis. He seemed but little inconvenienced and insisted upon leaving the hospital before the pseudomembrane had disappeared. Rendu notes that acute nondiphtheritic pseudomembranous laryngitis has been recognized since 1890 but occurs characteristically in children, with practically the same clinical signs as laryngeal diphtheria, and is even more serious than the latter owing to its tendency to extend downward to the entire bronchial tree.

Prophylaxis Against Infectious Diseases in the Macedonian Campaign.—Armand-Delille, Lemaire, and Paiseau (*Bulletin de l'Académie de médecine*, April 6, 1920) describe the results of the activities of the International Commission on Hygiene, originally created in 1915 by Major General Macpherson in Salonica. Although in the case of dysentery and malaria the efforts put forth came too late to do much good, the severe epidemic affections, such as plague, cholera, and typhus, were so controlled that the damage done was far less than in other armies on the Eastern front during the same campaign. As regards cholera, all the troops were systematically vaccinated, either with vaccine from the Institut Pasteur as in the French, Serbian and Greek armies or with Castellani's vaccine, as in the British army. No case of cholera developed among these armies, although a large focus of infection occurred at Koritza in the zone of occupation. Systematic vaccination of 10,000 natives was likewise carried out, rapidly arresting the epidemic. In the case of plague, a service for rat destruction and bacteriological study was set up at the French base, and succeeded in localizing the foci of infection, both at Salonica and Mytilene. Relapsing fever appeared in a rather extensive epidemic form in the native population and Greek army. Strict delousing measures prevented the spread of the disease to the Allied armies, among which only a few isolated cases developed. The measures against typhus fever included systematic delousing of the entire Serbian army brought over from Corfu. A similar service was established in the Russian brigade, in which a few fatal cases had occurred.

A Case of Meningoencephalitis Lethargica.—William W. Hala and Cyril M. Smith (*Archives of Neurology and Psychiatry*, February, 1920) report a case, clinically diagnosed as encephalitis lethargica, verified by observations antemortem and postmortem. From the clinical viewpoint the author's case was one of meningoencephalitis, with lethargy and involvement of the motor fibres of the third, sixth, seventh, tenth and twelfth cranial nerves. The etiological cause was a gram negative motile bacillus, unidentified, but probably belonging to some intermediate class of colon-typhoid-enteritidis group. Pathologically, the lesion demonstrated septic meningoencephalitis and ependymitis, with punctate hemorrhages and perivascular cell infiltration of the centrum ovale, corpus striatum and optic thalamus.

Disseminated Sclerosis due to Shell Concussion.—Ducamp and Milhaud (*Presse médicale*, May 5, 1920) report the case of a man who was temporarily buried by the explosion of a *minenwerfer*, remained deaf for two days, and then resumed his military service. One year later he felt pain in the left lower extremity, sometimes of lightninglike character, which came on with fatigue and passed off with rest. Later paralysis of the right arm and leg appeared, together with sphincter disturbances. Vision was impaired for a time. The paralysis was later partly recovered from, but the patient, on detailed examination, showed the various disorders of locomotion, motility of the upper limbs, reflex action, vision, sensation, voice and sphincters characteristic of disseminated sclerosis. A number of more or less similar cases have been recorded by other observers. The long delay between the trauma and the appearance of symptoms is ascribed to the gradual development of the central nervous lesions from the original capillary hemorrhages produced by the former in the nerve tissues.

The Tenue Phase of Plasmodium Vivax.—A. J. Chalmers and R. G. Archibald (*Journal of Tropical Medicine and Hygiene*, February 2, 1920) report a case of malaria in a British soldier, caused by two generations of plasmodium vivax, the parasite of simple tertian malaria. The patient's blood showed parasites in the peculiar tenue phase, which the authors believe to represent an attempt at asexual reproduction by fission, both simple and multiple. In one of the illustrations two parasitic rings are shown, joined by a narrow loop of protoplasm, but with only one ring provided with chromatin. Further steps are also shown, the last development depicted being one in which a single erythrocyte contains five connected rings with chromatin and one ring without chromatin. The whole process appears to be a throw back to a method of reproduction which may have been useful to some ancestor of the malarial parasites, but which is now devoid of practical importance and rarely seen. No trace of migration of the parasites could be found. The same patient afforded a good example of dermatitis scarlatiniformis due to quinine.

Mental Disorders Associated with Old Age.

Sir George Savage (*Journal of Nervous and Mental Disease*, March, 1920) discusses the medico-legal aspects of old age. Loss of memory, especially for recent occurrences, loss of self control and concentration, disturbed sleep, hysterical or emotional condition during which the individual is particularly prone to the influence of younger persons in his immediate environment, are some of the outstanding features of senile dementia. Senile melancholia is also frequent and hallucinations of smell and sight complete the list of manifestations.

A Case Presenting an Epidermoid Papillary Cystoma Involving the Third Ventricle.—Donald J. MacPherson (*Archives of Neurology and Psychiatry*, April, 1920) shows a case presenting an epidermoid papillary cystoma involving the third ventricle, the tumor probably originating either from a hypophyseal rest, or as a result of a developmental abnormality of the infundibulum. The clinical signs and symptoms of sixteen months' duration did not lead to a localization before death. Correlation of clinical and pathological findings has been complicated by the difficulty of separating local from remote and general effects and the paucity of data as to the normal physiological function of the structures involved.

Preparation of a Stable Vitamine Product and Its Value in Nutrition.—H. E. Dubin and M. J. Lewi (*American Journal of the Medical Sciences*, February, 1920) assert that they have prepared a stable vitamine product, an analysis of which shows its chief components to be calcium, expressed as calcium oxide, 10 per cent.; phosphorus, 15 per cent.; nitrogen, 3.5 per cent.; fat, 2.5 per cent.; iron, 0.3 per cent.; silicates, 5.6 per cent.; moisture, 10 per cent. The remainder goes to make up the rest of the phytin molecule—the main constituent of the product—which is a double calcium and magnesium compound of inosite phosphoric acid. It is not intended as a substitute for any method of treatment, nor is it meant to be used in infant feeding only, but is rather intended to be a valuable aid whenever its use is indicated.

Renal Calculus with Negative X Ray Findings.—A. Hyman (*Boston Medical and Surgical Journal*, July 15, 1920) tells us that negative radiographic findings in renal lithiasis are not infrequent, four such cases being observed within the period of a few months. Latent kidney stones are also not uncommon; in two cases there were no symptoms referable to the side on which calculi were found. The chemical analysis showed urates to be the predominating constituent in all four cases. The passage of a ureteral catheter unobstructed into the pelvis of the kidney does not prove the absence of a ureteral calculus. The wax tipped bougie is of value; it will every now and then demonstrate the presence of a stone when other means fail. Conservation should be the watchword in all operations upon the kidney. Nephrectomy should be practiced as a last resort, for despite negative radiograms and absence of symptoms, the opposite kidney may be the seat of calcareous disease.

Anthrax from the Shaving Brush and Primary Anthrax Meningitis.—H. W. Carey (*American Journal of the Medical Sciences*, May, 1920) tells us that a new method of anthrax transmission from the use of the shaving brush has been discovered during the war. The hair used in the manufacture of the infected brushes came chiefly from China and Siberia, to a lesser extent from the Argentine and Chicago. The hair was either not disinfected at all, or inadequately disinfected. The isolation of the *Bacillus anthracis* from the shaving brush is accomplished better by the inoculation of susceptible animals than by cultural methods. Meningitis due to anthrax may occur without any apparent point of entry. The spinal fluid is always bloody and contains the anthrax bacilli in large numbers.

The Capsule in Cataract Extraction.—Edward Jackson (*Archives of Ophthalmology*, May, 1920) says that the capsule of the crystalline lens can rarely cause any serious impairment of vision when left *in situ* after the extraction of senile cataract. Even the epithelium lining the anterior capsule is not a source of danger in this connection in senile eyes. Aftercataract is in most cases essentially composed of tissue developed from fibroblasts which reach the capsule during a period of inflammation following cataract extraction; such inflammation being especially favored by the presence of lens substance within the eye and outside the lens capsule. * Peripheral linear capsulotomy guards against the danger of such damage from the presence of lens substance in the anterior chamber quite as well as the more difficult and formidable operation of intracapsular extraction.

Foreign Body of Dental Origin in a Bronchus.—Carl Arthur Hedblom (*Annals of Surgery*, May, 1920) presents the following conclusions: 1, Aspiration infection of the lungs is most common in operations about the mouth following general anesthesia. 2, Symptoms may be immediate and continuous or there may be an intervening symptomless period of months or years. There may be no immediate symptoms. 3, The most constant and characteristic immediate symptoms are cough, dyspnea, wheezy respiration, and pain in the chest. The late symptoms in varying number and degree are those of pulmonary suppuration. 4, Late symptoms of foreign body infection often simulate phthisis, and that is the diagnosis often made. 5, Positive diagnosis rests essentially on history taking, x ray, and bronchoscopy. The history may be that of having swallowed the foreign body. 6, Bronchoscopy for diagnosis is indicated in any early doubtful case. 7, Spontaneous expulsion of small, irregular foreign bodies of high specific gravity, especially teeth, is always doubtful. Spontaneous expulsion often occurs only after an abscess has formed. 8, Bronchoscopy is the only treatment to be considered in early uncomplicated cases. In cases in which there is suppuration, thoracotomy for drainage gives the best results. 9, In fatal cases death is usually due to abscess, bronchiectasis, or gangrene of the lung, any of which may be complicated by empyema. 10, Tuberculosis may coexist with a suppurative process.

Torsion of the Left Testicle Followed by Gangrene of the Testicle and Epididymis.—R. E. Powell (*Canadian Medical Association Journal*, June, 1920) reports the case of a young man in whom, after violent gymnastic exercise, acute pain and swelling appeared within the scrotum and simulated acute epididymitis. At operation there was found torsion of the left testicle with strangulation of the vessels of the spermatic cord, which had led to gangrene of the testicle and epididymis. Castration was done and the patient recovered.

Effect of Therapeutic Doses of Mercury on the Kidneys and the Duration of Its Excretion.—L. G. Beinhauer (*American Journal of the Medical Sciences*, June, 1920) says that the excretion of calomel in ordinary therapeutic doses begins within six to twelve hours and is continued until the sixth day, depending on the size of the dose. A small dose is excreted as rapidly as a larger one, but over a shorter period of time. In so far as could be determined by the urine analysis the drug is excreted without bad effects upon the kidney.

Method of Performing External Urethrotomy Without a Guide.—G. R. Livermore (*Urological and Cutaneous Review*, May, 1920) describes his method in great detail, and then concludes that for those who do not thoroughly understand the steps of an external urethrotomy without a guide, or in cases in which there is so much scar tissue that a sound cannot be introduced to the face of the stricture, it is safer for the patient and much easier for the operator to do a preliminary suprapubic cystotomy and retrograde catheterization, thus locating the urethra behind the stricture and converting an intricate operation into a very simple one.

An Unusually Large Cyst of the Epididymis.—Abr. L. Wolbarst (*Urological and Cutaneous Review*, May, 1920) reports a case with these interesting features: The cyst was evidently purely retention in character, arising in all probability from a dilatation of a seminal tubule due to some obstruction in the vas deferens or some other portion of the excretory passages; it was unusually large in size—almost as large as a hen's egg; the blood vessels were clearly outlined on its external walls; spermatozoa were completely absent; the walls were very thin; there was no assignable cause for its development and no testicular involvement or malignant potentialities.

The Tuberculosis Problem and the General Hospital.—Max Taschman and B. Stivelman (*American Journal of the Medical Sciences*, May, 1920) say that ninety per cent. of the most competent observers in the field of tuberculosis consider it helpful and advisable to have beds set aside in the general hospitals for the purpose of study and diagnosis of cases of pulmonary tuberculosis before patients are sent away for treatment. These observers apparently mean sanatoria, for only about fifty per cent. of the large general hospitals which replied to a questionnaire have a tuberculosis service, and none of the others contemplate its establishment. The writers maintain that a tuberculosis service comprising ward and clinic in the general hospital is not only advisable but necessary.

On Deep Localization in the Cerebral Cortex.—E. G. Van't Hoog (*Journal of Nervous and Mental Disease*, April 1920) found from his researches that the supragranular layers of the larger animals consistently appeared higher than the corresponding zones in related small animals. There was, moreover, a corresponding decrease of the granular layer. The granular cells, he feels, should be considered matrix cells, not only in the fascia dentata but also in the neocortex. The supragranular cortex layers are receptor associative in accordance with Ariëns Kappers functional division, and the functional nature of the granules is also receptive and associative in the post central region.

Multiple Brain Abscesses.—Clarence C. Saelhof (*Journal of Nervous and Mental Disease*, April, 1920) describes a case of multiple bilateral brain abscesses, secondary to bronchiectasis, caused by the wedging of the lower lobe of the right lung into a pocket formed by kyphoscoliosis. As causative agents the *B. fusiformis* and anaerobic streptococci were isolated and cultivated from both the abscesses and the suppurating lung. The blood stream was considered the most probable route by which the infection travelled from its primary focus.

Determination of Magnesium in Blood.—W. Denis (*Journal of Biological Chemistry*, March, 1920) describes a method for determining magnesium in small amounts of plasma which has been adapted for use with the filtrate obtained after the precipitation of calcium in plasma or whole blood by Lyman's method. The procedure briefly consists in the removal of organic material contained in the filtrate from the calcium determination, the precipitation of magnesium as magnesium ammonium phosphate, and the nephelometric determination of the phosphate in this compound by the reagent of Pouget and Chouchak.

Human Arteriosclerosis: Some Remarks Concerning Its Etiology and Symptomatology.—George William Norris (*American Journal of the Medical Sciences*, June, 1920) leaves unsettled the question whether clinical arteriosclerosis may simply be an involutinal process, a part and parcel of aging; or of a mechanical or toxic origin. It seems to him more than likely that it will ultimately be shown to be the result of chemical changes associated with the bodily metabolism, which exert their effects upon the individual visceral, vascular and somatic cells, either directly or through the mediation of the ductless glands.

Two Cases of Fibrinous Bronchitis.—I. Chandler Walker (*American Journal of the Medical Sciences*, June, 1920) thinks that cases of fibrinous bronchitis would probably not be as rare as the literature would indicate if the sputa of patients were more carefully examined. The diagnosis is made only by the finding of long, branching bronchial casts in the sputum of patients who do not have tuberculosis, diphtheria, pneumonia, or any other primary bronchial disease. Fibrinous bronchitis is an idiopathic disease, the cause of which is unknown.

Proceedings of National and Local Societies

AMERICAN GYNECOLOGICAL SOCIETY.
*Forty-fifth Annual Meeting, Held in Chicago, May
24, 25 and 26, 1920.*

The President, Dr. ROBERT L. DICKINSON, of New York,
in the Chair.

(Continued from page 564.)

Sterility in the Female.—Dr. CHARLES G. CHILD, JR., of New York, said that in his series of cases the average period of sterility was three and one half years. In one case of seven years' duration the patient was cured in ten months. The average time from operation to the birth of the first child was 15.3 months, while seven patients gave birth within one year after operation. Seven of these patients were unconditionally sterile, due to tubal occlusion, and these subsequently bore eight children, who owed their appearance in the world absolutely to conservative surgery. These eleven women operated upon had, to date, borne sixteen living children, and eight were still in the child-bearing period. Such results as had been obtained in these cases should go far towards creating in the surgeon added respect for the art he practised, and a firmer belief in the value of conservative gynecology.

Errors in Gynecological Diagnosis Due to Misplaced Organs.—Dr. REUBEN PETERSON, of Ann Arbor, Mich., drew the following conclusions: 1. Mistakes in gynecological diagnosis arising from misplaced organs are not uncommon, as shown by the literature in which only a small proportion of such mistakes is probably recorded. 2. Such errors in diagnosis arise from either carelessness, or preconceived ideas of diagnosis whereby important facts in the history and equally important physical findings are either overlooked or ignored. 3. Such diagnostic errors can be averted by greater care in systematically considering with a free mind the facts in the case relating to the history and physical findings provided the latter are obtained through the employment of the most modern methods of examination. 4. In every case a preoperative diagnosis should be made and recorded in order to profit by mistakes revealed at the operation or autopsy.

The Gynecological Problem in Industrial Medicine.—Dr. HARRY E. MOCK, of Chicago, said that the scope of industrial medicine involved the supervision of the health of employees in industry and other problems connected with the factor of human maintenance. It included the prevention of diseases and accidents; the constant supervision of the physical conditions of the employees by medical examinations and frequent conferences; adequate medical and surgical care; industrial sanitation, and nursing service. Comprehensive medical systems had been installed in a great many of the large industrial plants of the country. Where women were employed, this health supervision had given a great opportunity to study many gynecological problems, and their effect upon the efficiency and desirability of women employees in industry. A common cause for absenteeism among women workers was dysmen-

orrhea. Personal observations of this condition among several thousand women employees in a large industry were given extending over a period of several years. Other gynecological problems met in industry included the frequency of venereal diseases among women employees where complete medical examinations of women were made; the frequency of pregnancy among girl workers and how this problem should be met; the effect of dress, diet, and habits upon the health and efficiency of women workers; the need of convalescent homes in large cities for the women workers. Industrial medicine presented a wonderful opportunity for studying certain medicosociological problems as related to the large group of employees.

The Treatment of Suppurating Wounds Following Abdominal Section.—Dr. THOMAS J. WATKINS, of Chicago, said that no sutures were removed on account of suppuration except when they cut deeply into the tissues, and no drains were inserted. No probing was permitted. Moist boric acid dressings were placed over the wound as soon as signs of suppuration appeared and were continuously applied until excessive redness disappeared. The moist dressings were used to keep the wound secretions from desiccating, thus promoting drainage. Experience had shown that a large amount of drainage would take place through very small openings when thus treated, that the drainage would be efficient, and that the suppurating surfaces, by virtue of atmospheric and intraabdominal pressure, would keep in relative apposition.

The author had used this treatment for about fifteen years and had found that the wounds healed quickly, that the treatment was painless, that the patient was not unnecessarily disturbed mentally, and that the ultimate strength of the abdominal wall was seldom injured by the suppuration. When the discharge ceased no open wound remained to heal by granulation. Antiseptic solutions were not employed as they injured the tissues more than they harmed the bacteria. Irrigations, drains and the like did much damage to the delicate tissue repair which was present in the healing wounds. Photographs were presented of wounds which had suppurated and showed no evidence that there had been any suppuration. It was not uncommon for patients who had had suppurating wounds to recover entirely, and leave the hospital at the end of the third week after operation.

A Neglected Form of Cervical Endometritis.—Dr. HENRY T. BYFORD, of Chicago, stated that as a result of acute cervical endometritis a permanent exudate was sometimes left about the internal os uteri, which for descriptive purposes he called a constriction ring, although in reality it was merely a greater thickness of the mucosa at that point. This constriction ring not only produced the characteristics of stenosis in many cases, but gave rise to the ordinary symptoms that were usually attributed to endometritis, such as backache, reflex stomach disturbances, malaise, dysmenorrhea, intermenstrual

pain, menorrhagia and sterility. The number and severity of the symptoms varied greatly in different patients, depending in part upon the interference with the patency of the lumen, the chronicity and the associated pelvic conditions, and partly upon the patient's general resisting powers and nervous habits. The diagnosis was made by means of the sound which detected a tender area at the internal os and which caused more or less bleeding. In the more chronic cases firm pressure exerted by a dilating wound produced a slight discharge of inspissated mucus which adhered to the sound. The treatment called for gradual progressive dilatation with round dilators under the strictest aseptic and antiseptic precautions, and later stimulating applications of iodized phenol. The occasional failure of an Emmet trachelorrhaphy to cure the symptoms was laid to a persistence of such an exudate at the internal os.

Hemorrhages Into the Pelvic Cavity Other Than Those of Ectopic Pregnancy.—Dr. RICHARD R. SMITH, of Grand Rapids, Mich, stated that although ectopic pregnancy was by all odds the most frequent cause of hemorrhage within the pelvic cavity, it occurred occasionally from other causes. The most frequent source of such hemorrhage was the ovary. For clinical purposes they might be conveniently divided into three groups.

1. Caused by a ruptured Graafian follicle or corpus luteum which occurred most frequently in young women, and in which the symptoms rather closely resembled an ectopic pregnancy. Many patients had been operated upon also for supposed appendicitis. Blood might be found in lesser amounts or in amounts large enough to cause grave symptoms. A microscopical examination ordinarily showed a normal Graafian follicle or corpus luteum.

2. The second group was not uncommonly designated as hematoma ovarii. Here one was dealing with a distinctly pathological condition, which might be evidenced with hematomata into the Graafian follicles, with secondary changes following in the ovarian structure. This condition was rather frequently associated with fibroids or with some inflammatory trouble with the appendages. In other cases no such association apparently existed nor was the cause clear. In young women it was sometimes the cause of severe dysmenorrhea.

3. A group of hemorrhages associated with ovarian tumors (cystic or solid) of considerable size, in which the bleeding occurred into the tumor or from it into the peritoneal cavity. Such bleeding tumors were commonly the seat of a twisted pedicle or of inflammatory adhesions; also a ruptured pedicle had been the cause.

Although the tube might on rare occasions give rise to hemorrhage without the cause being evident, in most cases the reason for such hemorrhage was apparent. A tube involved in the twisted pedicle of an appendage was a good illustration of such hemorrhages; occasionally it was found associated with the thickened tubes of an old infection. Such hemorrhages were small in quantity in the reported cases and the condition should be easily differentiated from ectopic pregnancy. Intraperitoneal hemorrhages from fibroid tumors formed a very interest-

ing group. Wallace reported seventeen collected cases and Gerstenberg one. The hemorrhage was often severe and the mortality had been very high (thirty-five per cent.). They occurred from dilated veins or from a rupture of the tumor itself.

Presidential Address.—Dr. ROBERT L. DICKINSON, of New York, stated that in all other departments of medicine and surgery the war made an inventory of men and methods. Gynecology should now conduct a complete self survey. The specialty was limited but large, the procedures being few, yet gynecological operations, as studied in clinical congresses or in daily operation notices of large cities, omitting lesser operations, were shown to comprise one fourth of surgery. Operation was required in less than one tenth of patients with disabilities peculiar to women, obstetrics being excluded. The future problems that gynecology was alone qualified to solve were considered. The first was its own portion of a standard nomenclature, whereupon the new census volume was presented. The operation nomenclature was under way. Standards were defined as the best present practice, widely studied, fairly epitomized, succinctly written down, warily applied, both flexible and progressive. There was need of taking stock of obstetrical and gynecological clinics. The lack of leaders was deplored, one cause shown by the war census being a want of hospital connection, only one medical man in twenty-eight, and one surgeon in four having such connection. Therefore, deliberate selection, training, full knowledge concerning specialists, teaching centres for the future were urged, and the carrying of obstetrical education directly to the practitioner in his own locality. Women should be given hospital opportunity, so that American women might prove themselves as good as British.

What were some of the sociological problems? Sterilization of women by simple means, with tests of tube patency; artificial impregnation; contraceptives; the definition of normal sex life; the doctor's section of sex instruction; and the extension of routine pelvic examination before marriage and the harder forms of industry. He advocated the establishment of a journal under the auspices of the society; also gynecological centres in libraries and museums, including a slide library, loan charts, and a studio. Finally, action was considered looking toward certification of specialists, such certification to hold good some ten years at a time.

The Development of Prenatal Care and Maternal Welfare Work in Paris Under the Children's Bureau of the American Red Cross.—Dr. FRED L. ADAIR, of Minneapolis, said that prenatal or antenatal care was that part of a public health program which had as an ultimate object the beneficial influencing of the health of the offspring by surrounding the mother with proper conditions during the period of pregnancy. Any complete health and social welfare program should include two public welfare activities, i. e., maternal and infant welfare, which were closely related and should be very carefully coordinated. These activities were intimately bound up with the family and concerned particularly the mother and child. While these two

subprograms were more or less closely related to all the other public welfare work, they had more points of contact with each other than with the rest of such activities. From an administrative viewpoint these two activities should be comprised in a maternal and child welfare program, but from a medicosocial viewpoint the work should be handled by experts in the different lines of work.

The objects of the maternal welfare program were: 1. To develop healthy parents, especially mothers who were intelligently trained; 2, to bring them through life to maturity capable of bearing and rearing normal children; 3, to reduce the maternal, fetal and newborn morbidity and mortality to the lowest possible level; 4, to leave the mother with a desire and capacity to bear and rear children properly in a sufficient number and of such a quality as not only to maintain the integrity of the human race, but constantly to improve its character. The family should be protected from various detrimental influences by education, legislation, and proper help and advice. This meant that each family should have a normal economic status, proper housing, good sanitary surroundings, proper advice, and care in case of physical or other needs resulting from disease, economic reverses, or distress of any kind. Some of the medical problems which vitally affected the individuals and the family were those dealing with tuberculosis and venereal diseases. These activities were very closely allied to maternal welfare work.

The legislative program included those laws which were designed to protect the family unit in health, economic independence and happiness, or to prevent any invasion by medical or social disease. The relief of social distress and disease was not less important than the cure of physical ailments and diseases. For the happiness and wellbeing which could be brought to the individual mother and those associated with her by intelligent guidance, sympathy and help were unmeasurable.

The Importance of a Followup System.—Dr. GEORGE W. KOSMAK, of New York, asked whether a recently delivered mother in either private or hospital practice was accorded as much attention in a followup sense as a patient recovering from medical or surgical illness. During the past decade the development of prenatal care might be regarded as one of the most important advances in obstetrics. In view of the tendency to injuries resulting in invalidism remaining unrecognized in the usual postpartum examination, a discharge of the patient should not be made for at least three months after the birth of the child. During this interval at least two or three examinations of the patient should be made. It was possible to treat minor traumatic and other lesions during this period and avoid later complicating conditions resulting in invalidism.

A survey of forty-eight American maternity hospitals showed that thirty-six of this number maintained some sort of followup system but in the majority of the latter the patients returned only if abnormalities developed. The admission was made by practically all observers that a followup system for obstetrical patients was not only desirable but necessary. Certain difficulties must be acknowledged

in instituting such a system but with the better education of the patient the realization of the need would become apparent to her and her family. A regularly organized postpartum clinic should be part of the equipment of every maternity hospital and in connection with the same an organization of social service workers or followup nurses to visit the patients in their homes was essential. The necessity of more prolonged postpartum observation should be included in every scheme of hospital standardization and the shortcomings of institutional work in this field applied with equal force to private patients. The advisability of some form of maternity insurance might do a great deal to obviate some of the difficulties connected with the scheme of more prolonged postpartum care of obstetrical patients.

An Analysis of the Failures in Radium Treatment of Cervical Cancer.—Dr. FREDERICK J. TAUSSIG, of St. Louis, stated that radium treatment of uterine cancer should be kept in the hands of the gynecologist rather than the röntgenologist, but such a gynecologist should seek preliminary training in the use of radium and must have continued opportunity for observation and treatment of cancer cases in order to reduce mistakes to a minimum. Good permanent results could be obtained in a certain proportion of cervical cancers with amounts of radium not exceeding one hundred to one hundred and fifty mgs. of the element, though the use of large amounts in the form of emanation would doubtless decrease complications and increase the number of cures to some degree. If possible, all necessary treatment should be given within the first six or eight week period before sclerosis had set in and rendered the cancer less accessible and the normal tissues more susceptible to injury.

Tumor filtration or light metal filtration together with intracervical application did most good and least damage; twenty-five hundred to thirty-five hundred mgs. were usually enough to give results in the favorable cases. In the absence of the Bailey bomb and large amounts of emanation, well directed and prolonged x ray from six to eight portals would usually affect the parametrial and glandular involvements. Prolonged necrosis and fistulas were due to repeated treatments, to vaginal applications and to heavy gamma radiation or to a combination of the three. Rectovaginal fistulas were more frequent and vesicovaginal fistulas less frequent after radium treatment. Operation was to be preferred in all operable cases where the patient was under thirty-five years and in the early operable cases where the patient was beyond this age. Radium was to be recommended wherever obesity, lung, heart or kidney lesions made operation difficult or dangerous, and in advanced operable, borderline and inoperable cases, but not in the advanced inoperable group with cachexia. The advanced inoperable cases had better be treated with acetone, since radium increased the tendency to fistulas and pain in most instances. These views were based on an experience extending over two and a half years in the treatment of eighty-six cases of cervical and vaginal cancer and six cases of vulvar cancer, in which radium or a combination of radium with operation was employed.

(To be concluded.)

NATIONAL HEALTH PROBLEMS.*

By HUGH S. CUMMING, M. D.,
Washington, D. C.,

Surgeon General, United States Public Health Service.

In the last analysis most health problems are in a certain sense local problems, and the Federal Constitution, which as handed down by our forefathers I am old fashioned enough to believe is the wisest instrument of government ever devised by man, sets distinct limitations upon federal activities in public health; limitations which are apparently overlooked by many enthusiastic *workers*—and others. For such problems, I look upon the United States Public Health Service as a reserve to be called upon by state and local authorities when the forces of disease or diminished economic efficiency consequent therefrom are for any reason more than local or state authority can subdue, or in which they request federal aid and cooperation.

There are, however, problems concerning the nation's servants, be they military or civil, and problems involving foreign and interstate commerce in its broad sense which clearly require national action. There are also other problems in preventive medicine which are naturally federal in scope. In nearly every great campaign there arise crises and battle is forced at some points not of our choosing, but which require for the success of our war a temporary withdrawal or weakening of forces at points which we know are our ultimate goal. Two such crises are now before the Federal health service, both consequent upon the World War. One of these is the prevention of the introduction into America of three great epidemic diseases, typhus fever, cholera and bubonic plague.

Detailed in 1918 in charge of Service activities in Europe, with especial reference to sanitation of returning troops and the inspection of ports of Europe with reference to resumption of trade and immigration, president of the Interallied Medical Mission to Poland, the American delegate to the International Convention of Public Health, and with twenty-five years of experience at home and abroad, I may be considered a fairly competent authority, and, in my opinion, there never before has been so grave a danger of the introduction of these diseases. For six years, plague, pestilence, famine and death, the four offspring of war, have ravaged Europe. So

far as Western Europe is concerned, there was comparatively little danger to us, so long as the war conditions continued, because of the absence of trade and the constant supervision of troops, though even in Holland there was a sharp epidemic of typhus in the winter of 1918-19, and occasionally rat plague at a British port. These conditions have changed, commerce and emigration have been resumed. In central and eastern Europe, the near Orient and Mediterranean littoral conditions are more menacing. It should not be forgotten that while commerce has been resumed, war, famine and disease are still raging.

There have been for several years thousands of cases of typhus fever in Poland and elsewhere in central and eastern Europe, including ports. Much to our surprise, we found last year no true Asiatic cholera in Poland, even among the Bolshevik prisoners, among whom were Chinese, Tartars, and others from cholera areas. This year reliable information leads us to fear an epidemic in Southern Europe and the near East. The third disease, plague, is much more insidious and difficult to control. Fifteen years ago Sir Patrick Manson in my quarters at the San Francisco quarantine station predicted that within twenty years plague would be pandemic unless it could be stopped by our quarantines. We now know that plague infection may persist among rats on a vessel for months before personnel are infected. Once it obtains a foothold in a port, it may persist for years until the rat population is starved and built out, and it takes millions of dollars to accomplish this.

In every Mediterranean port visited by me from Barcelona, Spain, to Constantinople human or rat plague or both were or had recently been present; in many it was endemic. Plague, human or rat, has been occurring with disturbing frequency at British ports, as well as elsewhere, and there have recently been sharp human outbreaks in several European ports. Generally speaking, the permanent stone structure of the quays, docks, and warehouses of Europe are not conducive to a long continued epizootic among rats, but in most of our American ports wood frame wharves and warehouses are ideal harbors. The great difficulty and cost of eradicating plague from such ports has been shown in New Orleans and San Francisco. The danger from cholera carriers was shown a few years ago when the Public Health Service found carrier after carrier in emigrants arriving from Naples despite the long voyage.

*Read before the Philadelphia County Medical Society, May 12, 1920.

To lessen the danger from plague the Public Health Service is requiring periodical fumigation of all vessels and the fumigation of vessels from Mediterranean and certain other ports, while trained medical officers are now in Europe. I am glad to say that the pending Sundry Civil Bill provides for the purchase and taking over of the New York, Baltimore and Texas maritime quarantine stations. It is quite conceivable that if the present conditions abroad continue or become worse that the Federal government may deem it wise to take additional measures of safety by restricting emigration from certain dangerous areas.

I hope that our respective state and local authorities will cooperate by vigorous deratization of cities, especially ports, looking into water supplies, and the improvement of housing and public baths. It may be added that the Federal government is urging such a revision of the International Sanitary Convention of Paris of 1912, to which over thirty nations are signatory, as will insure the recognition of cholera carriers, of rat plague, and of typhus, and a reliable reporting of disease.

The second great problem consequent upon the war, thrust upon the Public Health Service, is the hospitalization and care of the sick, wounded and disabled, discharged soldiers and sailors. These men to whom the country and indeed civilization itself owe so much are primarily the wards of the Bureau of War Risk Insurance, and, after convalescence, of the Federal Board of Vocational Training, the medical staff of both organizations being furnished by the Public Health Service to whom has been assigned by Congress the care of the sick and wounded.

The duty has been a difficult one in some localities, at times almost insuperable. Generally, there were insufficient hospital facilities, especially for neuropsychiatric and tuberculous patients when the war began; there has been little construction for six years, and the normal increase of population increased the deficiency. The army took over for its emergency many civil hospitals, and such of the temporary camp and evacuation hospitals as it has not needed have been transferred to the Service, but many of them, because of location or deterioration of frame buildings, are unfit for our needs. At present, the Service has about 16,000 men in fifty-two hospitals either owned or leased by it and in about 1,800 civil hospitals under contract. The number needing hospitalization is increasing at the approximate rate of 1,200 a month. Many of the institutions now in use are unsuitable and we are constantly being pressed by civil authorities to release institutions. I sincerely hope that Congress will appreciate the necessity of appropriating sufficient money to carry out the building program presented by the Public Health Service to provide for the number of patients, approximately 35,000, which we expect to reach in three or four years.

Some public health agencies may have misgivings that this duty will absorb too much of the personnel of the Service. I think this view a narrow and erroneous one. The work in a very direct sense is largely preventive medicine and toward the public health. For example, one third of the patients are

tuberculous, one third neuropsychiatric, and taking care of the tuberculous and psychiatric among nearly five millions of our population will meet two of the nation's important health problems. Furthermore, it is hoped that many of the hospitals will become centres for the development of better means for the cure and prevention of disease.

That group of communicable diseases known as the venereal diseases has for centuries been an unsolved problem, the grave importance of which has been brought to the attention of the general public as a result of our entrance into the war. He is indeed an optimist who imagines that this very serious problem has been overcome or even that the complete solution of it has been found, but I am convinced that it is to be best found in teaching the dangers of the diseases and in religious, moral and ethical training, rather than in coercive legislation alone, though proper legislation and its enforcement are necessary adjuncts.

There are other serious questions which affect the health, efficiency and welfare of the nation, such as malaria, typhoid fever, and general rural sanitation, child hygiene, and industrial diseases, which can be met efficiently by a cooperation of the Federal, state and local authorities. It will be well to consider the main Federal governmental agency interested in and responsible for disease prevention in the United States and its relation to state and local agencies.

The United States Public Health Service has been built up on the old Marine Hospital Service. For over a hundred years it has been growing. During that time Congress has imposed one duty after another until now it practically has all of the authority of law to protect the health of the nation which under the Constitution can be granted to any Federal agency. If it had annual appropriations commensurate with the authority granted, the country could expect dividend returns in the way of disease prevention that would be astounding. Even now it has an organization and funds which are the equal of any national health agency in the world. Beginning in 1798 with a fund obtained by assessing each sailor of our merchant marine twenty cents a month, it will spend this fiscal year for health work over \$2,400,000 in addition to over \$17,000,000 on its hospital relief work for the War Risk Insurance patients and other beneficiaries of the Service.

During the war the President constituted the Service a part of the military forces and its war record is one achievement to be proud of. It detailed officers to the Army and Navy, maintained sanitary zones about the camps and cantonments of the Army and had supervision over the health of many large war industries.

Within the boundaries of the camps themselves the Army health authorities were responsible for proper hygienic conditions. In the extracantonment zones the Public Health Service, in cooperation with State and local health authorities, was responsible. Aided by funds from the American Red Cross and local authorities, the Public Health Service established complete health organizations in fifty-one extracantonment zones. In all, the Public Health Service expended \$1,201,909, the American

Red Cross \$507,000, and the States and local authorities, \$650,000. The civil population protected by these organizations was approximately three and three quarter million persons, in addition to the military population.

It is not possible in a paper of this kind to enumerate all of the work done, but to illustrate: Two thousand five hundred miles of ditches were dug and 1,200 square miles of swamp territory drained, and an antimosquito zone—one mile in width—was established around each camp. It is a well known fact that malaria, which was a serious potential disability factor about many of these camps, was practically eliminated from the soldier population, and only 3,160 cases were reported to the Public Health Service during the malaria season of 1918 among the civil population of three and three quarter million, a rate of eighty-three in 100,000. From such data as were obtainable for previous years this was a tremendous reduction in the malarial rate in these communities. These results may well be compared with those in Panama, especially since they were obtained, not under military conditions, but through the voluntary work of a civil population.

After the war Congress, in providing for the medical and surgical care of the discharged and disabled soldiers and sailors, appropriated over \$10,000,000 for hospitals for the Service and made the discharged and disabled soldiers and sailors beneficiaries of the Service. During the year the Service will spend over \$17,000,000 for the maintenance of this medical care.

The Public Health Service has an organization consisting of a bureau with seven divisions and 450 employees in Washington and a field force of 593 commissioned officers, consultants and local medical men, and 8,100 other employees. It has fifty-two hospitals either owned or leased, and contracts with about 1,800 civil hospitals; ninety-one immigration stations; ninety quarantine stations; thirty stations for investigation and prevention of disease; thirty-four states are organizing with the Service a system of morbidity reports. The Venereal Disease Division has organizations working with the health authorities of forty-seven states. Some of its medical officers are detailed to advise and cooperate with other federal agencies and state health authorities. The Federal Government is responsible for the control of international and interstate spread of disease; the state governments, for the interstate and intrastate spread of disease; the local governments, for the intercommunity and intracommunity spread of disease.

The common responsibility is the control of disease. One case of any preventable disease is a matter of joint concern for national, state and local health agencies. Disease carriers do not recognize county and state lines. Once introduced into intrastate and interstate traffic a disease may cost millions of dollars and many human lives. The rational and businesslike method of disease prevention should begin at the bedside of the first patient or before and not wait until it reaches epidemic proportions. Applying such a business principle would make it imperative that the national, state and

local health agencies work together—form a joint partnership, if you please—and each bear its proper share in the work and expense. If Congress should recognize this principle and authorize such a partnership, the amounts now spent in the cooperation with the states would have to be greatly increased and a plan or organization would have to be carefully worked out so that each party to the partnership would meet the obligations and expenditures according to their respective responsibility.

The Public Health Service, owing to its size and present position in the field of health protection, would constitute the foundation upon which to build the federal health agency in such a partnership. The other federal agencies now authorized by Congress to perform certain health functions would necessarily have to be brought into the organization and their work correlated with that of the Public Health Service, in order to constitute a smooth working machine. In state and local organizations, where there are several legally authorized agencies performing health functions, these would have to be brought together and their work also correlated.

In the formation of a partnership of this kind volunteer health agencies now organized and working in the field of preventive medicine should be recognized and made a part of the machinery, but it should be distinctly understood that such agencies are auxiliary to legally constituted health agencies. However, they could be utilized to great advantage in this partnership owing to the elasticity of organization and the possibility of utilizing funds for work not authorized by law. But in the end these volunteer agencies should be brought under either federal, state or local laws and form a legal part of the health machinery. The control of disease is a governmental function and in a democratic government all agencies should finally come under authorized legal authorities, otherwise our Government would fail to be a democracy and would be subject to control by volunteer agencies who are not directly responsible to the people.

The war experience, as brought out by the results of the physical examination of the draft boards, has so impressed the Public Health Service that it has already presented to Congress a program intended especially to meet after war health needs. The fundamental principle in this program is federal cooperation with state and local health agencies and by far the larger part of the two million dollars requested of Congress would be spent along the Lever plan of federal aid extension.

When the organization of the triple partnership is complete it must be recognized that the Federal Government would have to bear its just proportion of the expenses in the state and local health machinery of forty-eight states and over four thousand local health jurisdictions. (There are about 3,000 counties and about 1,300 cities with a population of 5,000 and over). At the conference of state and territorial health authorities with the Public Health Service, I intend to discuss the subject of federal health organization and present for discussion by that conference a definite plan which would lead to concerted action of a constructive character.

EUGEN STEINACH'S WORK ON REJUVENATION.

BY A. GRANET, M. D.,
New York,

Instructor in Medicine, Columbia University.

While the lay press is heralding in its usually sensational manner the demonstration of the methods of transplantation of sex glands, I thought it would be interesting for the medical profession to get acquainted with the fascinating and far-reaching results of the elaborate experimental work in this field by Professor Eugen Steinach of Vienna. His researches date back many years. In 1912 he submitted for safekeeping to the Scientific Academy of Vienna the manuscript and protocols of his preliminary work on the subject in order to establish priority and to continue further research work.

In 1913, at the International Congress of Biology in Vienna he demonstrated experimentally artificial sex mutation in young female or male animals by transplantation of the opposite secretory gland (*Pubertätsdrüse*). His last and complete publication bears the title: *Verjüngung durch experimentelle Neubelebung der alternde Pubertätsdrüse* (rejuvenation through experimental regeneration of the aging interstitial gonadal gland), and was recently dedicated to Professor Wilhelm Roux of Halle on the latter's seventieth anniversary, and first published in Roux's *Archiv für Entwicklungsmechanik*, Vol. 46, 1920, and later edited in book form by Julius Springer, Berlin, 1920.

The outstanding features of his work are:

1. The conception and anatomicophysiological definition of the puberty gland (*Pubertätsdrüse*) as the internal secretory portion of the gonads. This consists of the interstitial cells in the male and of the lutein cells in the female.

2. He observed in animals with protracted rutting periods alternating stages of overdevelopment of the interstitial gland and the generative gland proper; this periodical and alternating overdevelopment occurs in the evolution of every individual, the interstitial gland predominating in infancy, attaining its maximum development at puberty and adolescence when the general growth and vital energy of the organism is also at its maximum. At this time the generative gland increases in power and both the interstitial and generative portions continue to be equally active or nearly so until climacterium sets in, after which the recession of the interstitial gland progresses rapidly and brings about all characteristics of senility. He contends that senility is not due to an ultimate using up of all organs, but to the lack of potential stimulus due to the degeneration of the interstitial gland.

3. The possibility of inducing experimentally the regeneration of the interstitial gland even after senile degeneration has taken place and all the characteristic marks of senility have appeared, in animals as well as in man. This he obtains by making use of the oscillating balance of nature in the mixed gland, by artificially inhibiting the generative portion and thereby causing a compensatory regeneration and revival of the interstitial portion, with all its rejuvenating effects, and the recession and disappearance of the characteristics of senility.

4. The means to accomplish this are: a. The simple ligation under local anesthesia of the vas deferens. This causes a regression of the generative gland and a compensatory regeneration of the interstitial portion (*Pubertätsdrüse*). A one sided operation is sufficient in all cases and has the advantage of preserving in addition the power of procreation. For obvious reasons the ligation of the fallopian tube in the female does not produce this result. b. Repeated mild exposures of the gonads to the x ray is a slower but just as effective means of obtaining the same results for both the ovary and testes. c. Finally the effects of rejuvenation may be experimentally produced—as we know—by transplantation in the old of the respective gonad of a young animal of the same species.

For the male the method of choice is the ligation of the vas deferens, for the female the x ray exposure. These are in short the fundamentals of the laborious experimental studies of Steinach and, as we see, they represent a great advance over the efforts of Brown-Séquard, Hufeland, Metchnikoff and others to fight senility.

The preliminary work leading to this subject which was done by Steinach and his coworkers on birds, insects, amphibia and mammalia has also been of late related by Paul Kammerer (1). For years Steinach has bred and raised healthy generations of laboratory animals, has studied and observed their dispositions, habits, physical characteristics in all the stages of their development with particular emphasis on sex development and characters of senility. His conclusive experiments he made on rats. He shows with an abundance of illustrations and photographs the influence of the interstitial gland on those animals. The animals which have acquired the characteristics of old age have a striking appearance: Their hair becomes bristly and sparse, they are timid and uninterested in the surroundings, the head is drooping, the spine is arched, the eyes have lost their tonus and their brightness, they do not seem to relish their food, they show loss of weight, muscular weakness, inability to climb; they don't fight other males nor pursue the females; they harbor parasites.

The same animals two weeks after the ligation of the vas deferens begin to change. They begin to pick up their heads, the eyes brighten and regain their tonus, they become lively, watchful and playful; their appetite returns; the hair begins to grow, becomes thick, soft and glossy; they gain weight, they move about with new vigor and agility, they fight other males let into their cage, they pursue and possess the female and bring forth new generations which grow up into normal adults.

This true rejuvenation is accomplished by the simple experimental procedure of ligating the vas deferens. The increased resistance to disease and actual prolongation of life of the operated animals he estimates at twenty-five per cent. After a time senescence sets in again.

The records of two men who underwent ligation of the vas are also given. One at the age of forty-four showed symptoms of premature senility, loss of weight, flabby muscles, myasthenia, senile depression, tremor and other senile characteristics. In this case complete return of vigor, alertness and

capacity for hard labor followed unilateral ligation of the vas. Another man, a merchant seventy years of age, was operated on with complete success. Two years after ligation he still enjoys the return of general muscular tonus, steady gait, good appetite, a good memory and interest in life.

In women of climacteric and postclimacteric age the beneficial effects of x ray applications for myomata and metorrhagias have been noticed by many observers. This improvement consists of general wellbeing, alertness, increased capacity for work, and was first attributed to the removal of the diseased condition. But Steinach contends that its real meaning is the warding off of senility caused by regeneration of interstitial ovarian structures.

Professor Bordier, of Lyon, also emphasizes the rejuvenating effects of the x ray applied in series. (For metorrhagias of the climacterium and for the treatment of interstitial fibroids.) After the second or third series anemic, withered complexions assume a fresh, rosy, youthful appearance. General debility and mental depression are replaced by a flourishing state of health. This is due to the fact that the interstitial portion of the ovary is not affected by the x ray; whereas colloidal-albuminoid precipitation occurs in the cells of the graafian follicles which are radio sensitive, the same as neoplastic cells. The affected cells disappear later by autolysis, menopause sets in, and the interstitial portion alone whose hormones produce the rejuvenating effect remains functioning. He has perfected a technic of application of massive doses in series which give positive results and secure protection from burns (2).

The effects of implantation are the same and according to Steinach's work the shrinking of the transplanted gland which occurs after varying periods is probably due to the atrophy of the sperm gland and should not prevent rejuvenating effects.

As we see, the experiments on men are but few. However his extensive and thorough work on animals, which is apparently beyond criticism, warrants further attempts and opens a very promising field. When the original publications of Professor Steinach's work reach this country American research workers will start control experiments.

Steinach's work aside from its applicability to senility could be made use of in the sexual neuroses. Functional impotence in man should be amenable to cure. The study of the behavior of cancerous growths in animals which have undergone ligation of the vas deferens would show how much our conception of cancerous age is worth. Arteriosclerosis may perhaps also be influenced. The much debated question of the harmfulness of masturbation may perhaps be settled in the light of Steinach's conception. The reason for the failure of the Brown-Séguard injections and of organotherapy with testicular glands becomes somewhat clearer. The manufacturers of glandular tablets may use testes of animals which have undergone ligation of the vasa deferentia with greater effectiveness; these could be used for patients unwilling to undergo ligation or x ray application.

I have based this paper on an article by Professor Wilhelm Roux, director of the Anatomical Institute of Halle, and one by Professor Dr. G. Holzknicht, chief of the Central Röntgen Labora-

tory of the Wiener Allgemeines Krankenhaus. These articles have appeared in the *Neue Freie Presse*, July 11th and 18th, and aroused the interest of the world in Professor Steinach's work. They were published as an appeal for the endowment of the Biological Laboratory of the University of Vienna.

HEMORRHOIDECTOMY.

By E. JAY CLEMONS, M.D.,
Los Angeles, Cal.

Before proceeding with an anorectal surgical operation it is necessary to make a proctoscopic examination. Instruct the patient to take no laxatives, to eat as usual, to take a tub bath the night before, and to have dry toast and black coffee for the previous meal. Prepare the patient for operation by administering a two quart cold water enema. With hemorrhoids prolapsed place the patient upon the left side, with knees flexed on abdomen and two pillows between the knees. Cleanse the parts and see that all instruments and solutions are cold, before proceeding with the operation, as heat applied to a visceral area gives pain.

The hemorrhoidal areas are three in number, one on the left and two on the right side. The median raphe lies to the left of the median line, in this region, both above and below, establishing the left hemorrhoidal area in the centre on the left side.

First stage.—Select a point upon the skin, a half inch to the left of the anus, and apply the cotton tipped end of an applicator which has been dipped in phenol, to anesthetize the skin, and to mark the spot for the insertion of the needle. When the place has turned white insert into the loose subcutaneous tissue a fine hypodermic needle attached to a half ounce metal syringe loaded with an eighth of one per cent. quinine urea hydrochloride solution. Inject this solution very slowly. At the first indication of pain stop and wait till the pain ceases, then inject a little more solution, being sure to inject so slowly that you do not hurt the patient or blanch the parts. While distending the tissues and producing pressure anesthesia use the one needle puncture, which is indicated by the opening on the white carbolized area; by so doing you prevent the solution running out of a former opening while injecting at another. After thoroughly distending the parts from this one puncture you find that just the tissues you wish have become distended and at the same time the solution has not passed the median raphe but you have prolapsed the hemorrhoid and brought out the anorectal line. Now pass a sharp ligature carrier threaded with number two ten day chromic catgut, beginning at the junction of the hemorrhoid and the raphe below at the anorectal line, pass deeply, penetrating the deep fascia coming out at the junction of the raphe above and the hemorrhoid at the level of the anorectal line.

Second stage.—Remove the ligature carrier, leaving double ligatures. Place forceps on each end of these ligatures. Grasp the skin with a vulsellum and draw on the stretch. While thus making traction on

the skin, place another vulsellum at the level of the anorectal line, one blade at each exit of the ligatures. This vulsellum is placed for two reasons; first, in case the ligatures are accidentally cut during the removal of the hemorrhoid you will have landmarks for placing other ligatures, and, second, a branch of the inferior hemorrhoidal artery enters the parts through these tissues. After placing the two vulsellum forceps, try the ligatures to make sure that they have not been caught within the grasp of the forceps. If free, cut the skin up to the ligatures.

Third stage.—Grasp the hemorrhoid with sponge holders and make traction slowly and steadily outward and downward until normal mucosa is exposed. Now tie each ligature separately around the base of the tracted hemorrhoid. In making the first knot, do so very slowly so as not to hurt the patient, as the parts have not been anesthetized. After making the first tie, the others can be made more rapidly as the first knot produces pressure anesthesia.

Fourth stage.—Cut away the hemorrhoid just external to the ligatures. Remove the vulsellum. If there is spurting from the inferior hemorrhoidal artery clamp and ligate it. Leave the stump of the hemorrhoid free. This stump is anchored by the ligatures to the deep fascia and cannot retract, but remains within the grasp of the anal sphincters. There is just enough stretch on the skin to bring the two edges together; at the same time do not interfere with postoperative oozing, which is very essential, as any interference with oozing produces edema.

Repeat the procedure by passing through the four stages with each hemorrhoid on the right side, except when dealing with hemorrhoids of the first and second degrees, in which cases the two right hemorrhoidal areas should be removed at one time, taking away twice the amount of tissue on the right as you did on the left side. It is always advisable to operate on both sides in each and every case of hemorrhoids to avoid future trouble.

The operative advantages of quinine urea hydrochloride anesthesia are as follows: While following the operative technic it is necessary to proceed so slowly that you do not hurt the patient, and by so doing you ascertain definitely the exact amount of pressure you are using. The quinine urea hydrochloride being nontoxic, the operator is enabled to prolapse the hemorrhoids and bring out the well defined median raphe, at the same time leave the intervening mucosa to cover the surfaces. In being able to regulate the amount of pressure, which is necessary to prolapse the hemorrhoids, it is possible to limit the distention and anesthetization of the skin to that portion which should be removed.

The postoperative advantages of the use of quinine urea hydrochloride anesthesia are as follows: First, being nontoxic there is no reaction, as occurs after the use of certain toxic drugs. Second, it is not necessary to use drugs of the nature of epinephrine hydrochloride to block off absorption, so there is no interference with blood pressure. Third, this drug being a mechanical irritant to the tissues, it causes the production of a plastic fibrinous exudate, which is a decided advantage when operating on hemorrhoids, as it brings the elements of repair to the parts, and after the first sanguineous exudation, minimizes postoperative oozing. Fourth, this

plastic fibrinous exudate having been thrown out and absorbed, a barrier is produced which enables the operator to get his patient safely on his feet and back to his work during the period the process of repair is taking place. Fifth, there is produced what is to the patient, at least, the main advantage, namely, that the anesthesia being postoperative it lasts during the period the fibrinous exudate is being absorbed, which is generally a week to ten days.

In conclusion, I will say that a patient proceeds to recovery with practically no discomfort, provided the operative technic is handled in such a manner as not to hurt the patient, that we receive his co-operation, and that he goes about his business; by so doing our patient is relieved pleasantly. If, while following the operative technic, we attack and remove only those tissues necessary to give relief, and by the use of the mechanical irritation of quinine urea hydrochloride we bring the products of repair to the parts, the healing will proceed quickly. Not having interfered with the higher centres, and by the use of quinine urea hydrochloride we produce a natural barrier, we can say that we relieved our patient safely. This makes me believe that we come near fulfilling the golden rule of surgery by "relieving our patient, pleasantly, quickly and safely" in a class of cases, composed to a large extent of patients who would generally be considered beyond the age for safe surgical intervention. The average age for the development of first degree hemorrhoids is forty years, and the time necessary for the evolution from first degree to third degree hemorrhoids is generally ten years, which brings the average age for the beginning of the third degree hemorrhoidal period at fifty. As this unrelieved pathological condition persists during life, it necessitates our dealing with a class of patients the majority of whom are in the fifth to the eighth decade of life.

605 HOLLINGSWORTH BUILDING.

GUNSHOT INJURIES OF THE CHEST IN CIVIL PRACTICE.

BY GEORGE P. MÜLLER, M. D.
Philadelphia.

The treatment of gunshot injuries of the chest constituted one of the most interesting and important chapters in the medical history of the war and in the volume of literature was hardly exceeded by any subject except, of course, that of wounds *per se* and their treatment by revision, suture, and antiseptics. To the French we are indebted for much that is new, particularly to Duval for the development of the method of wide open thoracotomy and to Petit de la Villeon for his method of extraction of late projectiles. Those of us who were unable to participate in the active surgical work of the war must get our ideas from those who did the work, must assimilate the literature, and be prepared to adopt the plan of procedure in the hospitals with which we are connected, when a gunshot wound is brought under our observation. Let us first glance, superficially of course, over the record of accomplishment, and the plans of procedure, during the

forty years preceding the war. The oldest book on surgery which I own is that of Agnew who was professor of surgery in the University of Pennsylvania from 1871 to 1888. Writing in 1878 he devotes considerable space to chest wounds but his opinions are entirely colored by the work of Otis who wrote the chapters on thoracic surgery (1). His descriptions, however, of wounds, of hemothorax, and other matters, are minute and really worth reading at this day, but he suggests nothing that is radical. In speaking of hemothorax he advises enlargement of the wound, if by so doing the outlet for the blood to escape will be increased.

Agnew was succeeded by John Ashhurst and at the time I graduated, (1899) we were told by him to practice rest, apply cold and give opium. If bleeding from the lung continued he advised reopening the original wound to allow the blood to escape or the performance of paracentesis to relieve the dyspnea. Gross, professor of surgery in the Jefferson Medical College, writing in 1882, had a fair idea of the pathological consequences of chest wounds. He classifies them as: Primary—shock, collapse of the lung, hemorrhage and pneumothorax; and, secondary—inflammation and accumulation of serum, lymph, and pus in the pleural cavity. He states that in the Russian Army at the siege of Sebastopol the mortality from chest wounds was ninety-eight and five tenths per cent.; in the British Army it was eighty-one and five tenths per cent. He states that the Russian surgeons relied chiefly upon the use of digitalis; the British upon copious venesection. In the Civil War, of 1272 cases, seventy-three per cent. were fatal. Gross makes no mention of thoracotomy and he recounts a fatal case where the ball was loose in the pleural cavity and was followed by violent inflammation and death in four weeks. Such cases he says "must necessarily be fatal." Venesection and purgation were his sheet anchors, and the patient was always placed with the wound dependent to allow the blood to drain out.

In an address before the American Medical Association in 1903 Rodman stated that the treatment for gunshot wounds of the chest should, as a rule, be a "masterly inactivity; absolute rest, cooling drinks, a little opium, and a sterile immobilizing dressing constituting the only treatment necessary in the majority of cases. Pressure may be relieved by aspiration and hemorrhage controlled by strapping. Any attempt to recover the ball would be fraught with danger and is rarely justifiable, as the bullet will continue to be harmless unless it has carried in septic material."

But Koenig in the same year stated that the treatment of these cases depends upon individual circumstances. In general, he says, it may be stated that only rarely is one justified in operating within a short time after the accident for the purpose of arresting hemorrhage. If two or three days after the injury the phenomena (respiratory distress, frequency of pulse, and elevation of temperature) increase, one should not hesitate to perform a thoracotomy. A rise of temperature and difficult breathing appearing at a later stage suggest infection, and constitute another indication for operation. Notice

that Koenig refers to the elevation of temperature accompanying the hemothorax *per se*. This has often led to the mistaken diagnosis of infection and precipitated a thoracotomy plus drainage, thus almost inevitably producing infection. In order to avoid the possibility of infection in a hemothorax, operation should be performed only under the strictest aseptic precautions; otherwise a hemothorax may be converted into an empyema. When the resorption is slow, one may remove the blood by puncture, and only when this proves unavailing is a thoracotomy justifiable. This advice relative to the treatment of hemothorax is practically that of Elliot (1919) one of the best of the English authorities on the subject. Elliot says "early aspiration must be the routine and if this is found to fail by reason of clot, then the chest must be evacuated at the earliest possible date by thoracotomy, without drainage."

In the following year Grunert advocated a more radical plan of treatment, and advised delayed thoracotomy for the removal of the blood clot in slowly developing hemorrhage and immediate operation in severe cases with an attempt to arrest the hemorrhage by ligature, suture or tampon. In 1905 the epoch making paper of Garre appeared in which he presented a statistical study of 700 wounds of the lung treated conservatively, dwelt upon the high mortality under such methods of treatment, and exposed some of the fallacies which had long influenced the treatment of these lesions. He pointed out that the general mortality was forty per cent.; in ruptures of the lung, uncomplicated by other injury it exceeded fifty per cent.; while stab wounds and gunshot wounds in the antiseptic era exhibited a death rate of thirty-eight per cent., and thirty per cent. respectively. He also clearly demonstrated that antiseptics as ordinarily applied could not favorably influence the internal wound which opened the lung itself; that the small calibre jacketed bullet was as dangerous as the old fashioned projectile; he also asserted that the often repeated view that bleeding spontaneously ceased in the collapsed lung had neither clinical nor experimental confirmation. The prime indications for operation, according to Garre, were hemorrhage, (abundant, persisting, or recurring,) and pressure pneumothorax not yielding to aspiration. While these were only present in five or six per cent. of cases of lung injury, they demanded prompt interference. He collected nine cases of suture of the lung, including one case of ruptured lung (his own) with six recoveries. The principles of treatment, as he laid them down, are not very different from those found useful by his followers; nor has his technic been greatly modified except as influenced by the facilities afforded by the development of differential pressure and a better understanding of the influences of pneumothorax and its relationship to drainage.

This paper of Garre's, and the invention of the negative pressure chamber of Sauerbruch and the positive pressure helmet of Brauer gave an impetus to thoracic surgery which has continued to this day. A number of valuable contributions appeared in the German literature particularly those of Küttner, Lawrow, Stöckey, Möller, Wolf, and Grassman,

and the question was discussed in detail in the Paris Surgical Society in 1907 and 1909. In 1911 a lively discussion between the abstentionists and the interventionists took place at the International Surgical Congress. Lenormant drew up the report for this congress and, according to his statistics, out of 1056 cases the rate of mortality was only ten per cent. In order to appreciate these figures correctly, it must be mentioned that they deal only with patients in civil practice, and that cases complicated by injury of the vessels of the hilum were excluded. The rate of mortality would be considerably higher if all cases of injuries to the lungs were included. A third of the mortality in Lenormant's cases was the result of infection and two thirds from hemorrhage. He favored expectant treatment. At that time the abstentionists seemed to have the better of the argument because, while the reasoning of the interventionists was perfectly sound and their operative indications the result of logical deduction, the statistical evidence was not always as convincing. Thus Lavroff quotes the results of a series of 257 cases occurring in Zeidler's clinic during a period of five years. Of these, 155 cases operated upon gave a mortality of thirty-six and seven-tenths per cent., while in 102 cases treated conservatively the mortality was only fourteen and seven tenths per cent. The author explains the figures by stating that the nonoperative cases were far less severe in character.

Holmberg reported a series of 324 cases, of which 266 were stabwounds, thirty-nine gunshot wounds, and nineteen closed or subparietal injuries. All but four of these patients were treated conservatively, that is, the stab wounds were carefully disinfected and sutured; the gunshot wounds were cleaned and an aseptic dressing applied, and the closed injuries were treated expectantly. The total mortality in this series in injuries involving the lung or pleura was fifteen and eight tenths per cent., of which the largest series, that is, the stab wounds, showed eight and one tenth per cent., the gunshot injuries thirty-seven per cent., and the closed ruptures, forty-seven per cent. In spite, however, of the statistics of Lenormant, Holmberg and others, the tendency of the times was towards active interference, especially in those cases when hemorrhage and pneumothorax threatened life.

Thus, in an article by Brewer (2), written in 1907, he advised the following: Treatment of existing shock; control of cough and restlessness by morphine; disinfection of the wound area, rest, strapping of the chest; aspiration of air in pneumothorax. If there is a progressively increasing hemothorax threatening life, the surgeon should freely open the pleural sac by resection of one or more ribs and attempt to arrest the hemorrhage by suture, ligature, or by packing.

But, five years later Brewer wrote that he would advise immediate exploratory thoracotomy in all cases of penetrating wounds of the chest which presented signs of hemorrhage threatening the life of the individual or seriously embarrassing respiration; in all cases where there was reason to suspect injury of the diaphragm, heart, or other important structures; and in all cases of large pleural wounds

where there is evident septic contamination and an open pneumothorax. He advised careful disinfection and aseptic dressings in penetrating gunshot wounds without symptoms or signs of a more grave injury, and in simple stab wounds without evidence of grave hemorrhage, pneumothorax, or injury to diaphragm or heart. In all cases of doubt, in wounds of the heart zone, or in the region of possible diaphragmatic injury, he favored exploratory operation as the safest method of treatment.

In 1911 Jopson read an illuminating paper before the Philadelphia Academy of Surgery. He pointed out that the binding indications for operation in penetrating wounds were as follows:

1. A wound which from its situation and direction would render likely a penetration of the heart, pericardium, or diaphragm.

2. Severe primary or recurring hemorrhage, as shown by the physical signs of hemothorax or external bleeding, or by severe hemoptysis with threatened aspiration of blood into the other lung.

3. Secondary hemorrhage, especially to be looked for in gunshot wounds.

4. Severe pneumothorax, especially when accompanied by symptoms of mediastinal and cardiac displacement, dyspnea, cyanosis, and threatened suffocation, and which is not relieved by aspiration; also when extensive and increasing external emphysema is present.

5. Secondary pneumothorax, which is always due, according to V. Möller, to suppuration or sloughing of lung tissue.

6. Empyema.

At about the same time Dorrance, also of Philadelphia, reported the results of some experimental work on animals and advised the following: "If hemothorax develops the chest wall should be opened as soon as the diagnosis is made; all clots and serum removed; the wounds in the lung sutured; the pleural cavity inspected and its toilet completed; and the chest wall immediately closed, the lung being expanded by either negative or positive pressure. The suturing of the chest wall is effected by means of the layer method. With absolute asepsis and a faultless technic, especially in the matter of gentle handling, recovery without the formation of adhesions ought to take place in a large proportion of cases. The worst that can happen when this method is used is the formation of an empyema."

There is no essential difference between this procedure and the method of Duval now so widely known, from his writings, from the paper of Moynihan and the personal observations of those at the front.

This brings us to the period covered by the war, and while the experience in chest surgery during this time has been enormous in material and in the lessons learned, I will attempt no extensive review partly because of the limitations of space, but mostly because it is so fresh in our minds and so familiar to everyone who has read. Also it seems to me that many of the problems that engrossed the minds of Duval, Piery, Gregoire, Gask, Elliot, and others, were bound up with the military aspects, with transportation, the lack of equipment at the front, the sucking open wounds, the shell fragments

and so on, with which there is nothing comparable in civil life. The real problems seemed to be these, and not the management of the infected pneumothorax at the base hospitals, over which so much was made in the early years probably from the shortage of experienced surgeons. I would especially commend the books by Duval and by Gregoire, and the articles of Piery, LeFort, Gask, Lockwood, Elliot, Bradford, Nixon, and Moynihan. On our own side the list is already a long one, and is headed by the contributions of Yates and Graham.

The conclusions of Nixon were published in April, 1919, and therefore represent the latest opinion of those experienced in war chest surgery, especially as he was associated at various times with Duval, Gask, Anderson, Roberts, and Lockwood. The indications for immediate operation indicated by Nixon are: 1, Hemorrhage, 2, injuries of the diaphragm, 3, open pneumothorax (traumatopnea), 4, stove in chest, 5, retained missiles, bone, and clothing, and 6, early acute infection.

The patient may be unfit for operation owing to: 1, Intrathoracic injuries, 2, severity of the external or complicating wounds, 3, loss of blood, and 4, collapse or shock due to cold and transportation. Nixon then states that it is the physician's province to decide as to the nature of the intrathoracic injuries, and he must form a definite opinion on the following points:

Is there a sufficient degree of the following to account for the severity of the symptoms? 1, Pneumothorax, 2, hemothorax, 3, collapse of lung, 4, laceration or hematoma of lung, 5, injury of heart, pericardium, or great vessels, 6, injury of diaphragm, or 7, injury of vertebræ or spinal cord.

Radioscopy and radiography are almost indispensable in order to reach a correct conclusion on these points, but it will sometimes happen that a patient's condition will not permit of immediate x ray examination. When this is so, the question is rendered easier rather than harder. The patient is thus unfit for any immediate operation save one of the following:

1. Immediate and rapid operation for the arrest of visible hemorrhage from the chest wall or thorax.
2. Arrest of hemorrhage from coexisting wounds.
3. Aspiration for relief of pneumothorax (usually valve pneumothorax).
4. Aspiration for relief of hemothorax.
5. Temporary closure of open pneumothorax.

Apart from one of these procedures, there remains nothing else to be done than to resort to measures for resuscitation of the patient. Now, it is obvious that in civil practice many of these indications will not be met. The wide open pneumothorax and the stove in chest from shell wounds are practically never seen. I say practically because Waters (3) recorded a remarkable case of shotgun injury in a boy in whom a great hole was torn in the anterolateral aspect of the left side of the thorax. The great majority of the wounds encountered will be stab wounds, or gunshot injuries with or without retained missile, and sometimes with complicating injuries of the heart, mediastinum, diaphragm, or the abdominal organs, particularly the stomach, colon, spleen, or liver.

Duval states "that bullet wounds of the lung are either fatal at once by reason of injury to a large vessel, or comparatively benign; the wound is either aseptic or seldom followed by grave infection. To this single factor their slight severity is due."—Further, he states "from a surgical point of view bullet wounds are of little interest, as they do not demand operative interference." But bullet wounds and stab wounds will be the injury in civil practice, and they will be of interest to the civil surgeon.

The problem before us is—shall we operate in all cases of stab or gunshot wounds of the chest, or shall we wait for the complications of hemorrhage, pneumothorax, or infection to ensue? If it were not for the occurrence of infection we might formulate: Early operation is indicated, a, when there is a rapidly increasing pneumothorax (from a valvelike opening); b, when the rib has been splintered by the bullet, and the fragments press on the pleura, or have been driven inwards; c, when hemothorax is large and seems to be increasing. Late operation is indicated: a, at any time when the pleural cavity appears to be infected; b, after six or seven days, when the patient's condition is excellent and he has been well studied, to remove clot or missile.

The crux of the situation, however, hinges on the matter of infection. If we wait until the patient is in excellent shape to stand the operation we may lose the opportunity to so cleanse the pleural cavity that aseptic conditions can be established. If we operate in all patients immediately, we will lose many from shock, and the mortality of the total will rise.

Shock must be met first. The patient should not be handled roughly or rushed to the x ray room. The chest should be immobilized immediately on arrival, however slight the injury may appear to be. The patient should be placed in bed, kept warm, and the wound dressed, and quiet assured by the aid of morphine. He should remain in the ward, propped up in bed and only examined immediately if serious signs, such as those of persistent hemorrhage or asphyxiation pneumothorax suggest the necessity of an immediate operation. Elliot in his interesting paper published in 1919 states that the reflex reaction to the chest wound causes a strong muscular contraction of the walls of the bronchioles producing the early cyanosis and dyspnea. Rest and morphine soon allay this spasm in most cases. If prolonged reflex constriction of the bronchial musculature occurs with cyanosis, dyspnea, and inspiratory retraction, operation is not well borne.

The diagnosis of hemorrhage and pneumothorax depends on the usual well known signs with the variations so well described by Bradford and others, viz., the elevation of the diaphragm, the small size of the chest, the tendency to complete or partial collapse of the lung in any area, the compensatory emphysema above and other known physical signs. The important point for the surgeon to determine is whether the hemorrhage is continuing or is progressive. If from the location of the wound of entry injury of the abdominal viscera is suspected immediate operation should be done. In those cases where all goes well and the proper surroundings

and skill are available there seems no reason why we should not routinely open the thorax in from five to eight hours after the injury in cases even where there is moderate hemothorax or where there is a retained missile. I admit that the mere retention of a missile is a debatable indication for operation but the dangers of fibrosis, abscess, or bronchiectasis are too real to be disregarded. It has been noted by all of us that hemorrhage and infection are the causes of nearly all the fatalities and many of the fatal hemorrhage cases are probably beyond help by reason of large vessel injury and death before operation can be attempted. But I am certain that some patients die who could have been saved by prompt thoracotomy. Early operation should avoid most of the fatalities from infection.

Where there has been delay and infection of the clot supervenes, immediate thoracotomy, removal of the clot and institution of proper drainage should be the rule. Finally, the missile should be removed from the lung at the earliest practicable time, usually within two weeks, if primary thoracotomy has not been performed.

It is not necessary to review the technic of operation. The so-called method of Duval may be taken as the standard procedure. The methods practised by LeFort should be studied, particularly when we undertake the removal of a bullet from the mediastinum. I do not know whether Petit de la Villeon's method will become the universal practice; the recent papers by LeConte and Moynihan highly praise its efficacy, but it demands a special apparatus and a technic made perfect by practice and gunshot injuries of the chest are not so common in civil surgery. In stab wounds involving the diaphragm the consensus of opinion favors the thoracic route but I have successfully operated in such a case by the abdominal route. The physiological principles involved in opening the chest and producing a pneumothorax must be well understood, and the brilliant paper by Evarts Graham should be memorized.

The use of inhalation anesthesia and particularly ether or chloroform is a factor adding considerably to the risk. Duval advises local or regional anesthesia, stating that the patches of pulmonary congestion which so frequently occur after operation, may be in some measure attributed to the effects of inhalation anesthesia as well as to the after-effects of the wound of the lung.

Lockwood and Nixon also use local anesthesia reinforced by gas-oxygen while the hand is inside the chest or if the patient is restless. On the other hand, Gask prefers chloroform, either by itself or combined with oxygen. Yates found that a safe sequence in practice was found to be as follows: after the effect of the preoperative hypodermic of morphine was apparent, the administrations of pure oxygen under no tension were started. Then very gradually the pressure was increased, and the administration of nitrous oxide started. Rapidity of induction of the anesthesia was undesirable. Avoidance of excitation and the production of gradually increasing inflation were essential. During the operation the proportions of the gas-oxygen mixture and the pressure transmitted to the trachea were varied to meet varying conditions. After the pari-

etal pleura was closed the amount of nitrous oxide was gradually reduced; oxygen under pressure was continued until the patient was conscious.

The tendency of most writers has been to minimize the importance of pressure apparatus or endotracheal methods in traumatic chest surgery, but Meyers considers it wrong to draw sweeping conclusions from the experience gained in the war. I have recently operated on patients with gunshot and stab wounds and performed exploratory thoracotomies for malignant disease under ether anesthesia on open gauze but believe that the method of Yates just described is the best. This method gives all practical requirements for intrathoracic surgery without necessitating deep anesthesia for the introduction of intratracheal or endopharyngeal tubes. Moreover, its safety and ease of control has removed the chief obstacle to a wider application of surgical therapy.

One of the problems of chest surgery is the difficulty of suturing the pleura, so as to hermetically seal the opening. Duval sutures the intercostal muscles and pleura together; Moynihan in his well-known paper advises wide separation of the pleura from the ribs in all directions (thus mobilizing it) before opening the cavity. I have not found this to be a very satisfactory procedure; however, in several cases. The reason lies in the persistence of the rib separation at the conclusion of operation. A number of surgeons overcome this separation by passing silver or bronze sutures around the ribs above and below the incision and tying with sufficient tension. Duval mentions particularly the importance of covering the resected ends of the rib with a staunch muscle suture because of the difficulty in bringing the pleuræ together here.

Time does not permit further discussion. Bastianelli's use of artificial pneumothorax in the treatment of chest wounds is quite interesting. He believes that the air keeps the lung from contact with the pleural membrane until complete expansion has resulted, thus minimizing adhesions at abnormal positions. Duval on the other hand considers a pneumothorax as an injurious process and urges its removal. Yates brings out the interesting point that in his dog experiments in which the phrenic nerve was sectioned, the dogs showed a remarkable freedom from distress and a reduction in the amount of postoperative effusion. This method has been used for the treatment of tuberculous cavity but taken in conjunction with Bastianelli's observations would repay further study of lung wounds.

The surgery of the chest is now well on its way to further development and improvement, but the tyro must keep his hands off until he has studied the work of the masters of the past and has digested the lessons of the war. While Duval's famous dictum, "that the surgery of gunshot wounds of the lungs must be governed by the principles of surgery as applied to any other gunshot wounds," requires a number of exceptions, it is in the main true, and should lead us to the point where we can open the chest as safely as we now open the abdominal cavity.

THE FUTILITY OF EXAMINING THE FILTRATE FOR THE PRESENCE OF OCCULT BLOOD IN THE GASTRIC CONTENTS.

By ANTHONY A. RUTZ, M. D.,
Brooklyn, N. Y.

Certain clinical and laboratory observations have recently impressed upon me the futility of examining the filtrate for the presence of occult blood in the gastric contents. Not infrequently it has been observed that gastric contents which on macroscopic examination contained blood when filtered become negative to occult blood tests. Furthermore, negative results from examination of the filtrate were too often at variance with the history and other findings.

In view of these facts it was determined whenever possible to make separate tests upon filtered and unfiltered gastric contents, and the results showed that in the majority of cases, in which the unfiltered contents were positive the filtrate was negative to occult blood tests. In a series of twenty-four cases in which the unfiltered contents were positive the filtrate was faintly positive in two and negative in the remaining twenty-two cases. In these twenty-two cases the unfiltered contents were strongly positive in thirteen, and faintly so in the remaining nine cases. Among the thirteen former were two cases of inoperable cancer of the stomach. In one of these the contents were light coffee ground in character and in four successive examinations the filtrate was negative.

The tests employed were at first both the guaiac and the tablet benzidin test of Dudley Roberts. As the results were similar, and as the latter is slightly more sensitive and far less time consuming, the benzidin test alone was employed in the later examinations of the gastric contents and in the subsequent experimental tests. The objections to the use of pure benzidin in the examination of the gastric contents for blood do not apply to the use of the prepared tablets, as these, though slightly more sensitive than the guaiac, are far less so than the pure benzidin. The test meals consisted of three Uneda biscuits and twelve ounces of water, the contents being removed one hour after ingestion.

It is evident from the foregoing that a distinct contrast exists between the filtered and the unfiltered gastric contents in their action toward occult blood tests. To determine the various factors responsible for this difference the writer conducted a series of studies:

1. Filtrates of solutions of blood (1 in 1000) in plain water or in sodium citrate solution were examined for blood. These were invariably as strongly positive as the solutions before filtration, showing that mere filtration without some change in the blood is not responsible for this difference.

2. Soda crackers were macerated in plain water and in gastric filtrates which were negative for blood. These gave negative tests showing that the presence of the crackers is not responsible for the positive reactions in the unfiltered contents. This is also evident from the fact that unfiltered specimens containing crackers are frequently negative.

3. That mucus itself is not responsible for this contrast is evident from the fact that often unfiltered contents, containing large quantities of mucus, are negative for blood. That the difference is not essentially due to the presence of blood in the mucus is shown by the following procedure: Stomach contents negative for blood were repeatedly filtered so as to remove the mucus. To these filtrates blood was added in the strength of 1 in 1000. They were then thoroughly mixed and incubated for one hour to represent more or less the physical and chemical changes which the gastric contents undergo in the body. At the end of one hour, these mixtures were examined for blood and were always found positive. These were then filtered. These filtrates were in the majority of cases negative and only at times faintly positive for blood, showing that filtrates of specimens containing blood become negative even in the absence of mucus. While the crackers and mucus are not the essential causes, they play a secondary rôle, as will subsequently be shown.

4. It has been proved that mere filtration without previous changes in the blood in the stomach contents cannot be the cause of the negative reaction in the filtrate. The blood undergoes definite changes in the stomach which are the cause of its total or partial disappearance in the filtrate. It is well known that in the presence of a weak acid, hemoglobin is decomposed into hematin and a globulin. The hematin is insoluble in weak acids, (occurring as amorphous granules, which by reason of their iron content have a high specific gravity and are strongly magnetic. That hydrochloric acid or, when this is absent, lactic acid is the essential cause of the contrast which exists between the filtered and unfiltered gastric contents, and that this is due to the fact that the granules of hematin formed by the action of the acid upon the hemoglobin are too large readily to find their way through ordinary filter paper, is evident from the following tests:

Three solutions are placed in separate beakers and are frequently mixed and incubated for an hour: a, 1 in 1000 solution of blood and water; b, 1 in 1000 solution of blood in two tenths of one per cent. hydrochloric acid; c, 1 in 1000 solution of blood in two tenths of one per cent. hydrochloric acid, with broken crackers added. After one hour, each mixture is tested for blood before and after filtration. In a, the filtrate and unfiltered solution are equally positive for blood. In b, the unfiltered solution is distinctly positive, while the filtrate is most often negative, but at times is faintly positive. In c, the unfiltered contents will be found positive, while the filtrate will be invariably negative.

As the only difference between a and b is the presence of hydrochloric acid, then the hydrochloric acid must be the cause of the absence of blood in the filtrate. It will be noted that the contrast between a and c is greater than that between a and b. It is evident that this must be due to the presence of crackers in c. The granules of hematin have a marked tendency to adhere to the larger particles of crackers in suspension, thus rendering filtration more complete. These tests were repeated with two tenths of one per cent. lactic acid solutions and the same results obtained as with hydrochloric acid. As

gastric contents are practically always acid, containing either hydrochloric or lactic acid, what has been shown applies more or less to all specimens.

5. That the hematin granules have a tendency to adhere to other particles in suspension is evident from the following observation: A weak solution of blood (1 in 5,000) is made in two tenths of one per cent. hydrochloric acid with broken crackers in suspension. The unfiltered mixture, after standing for an hour in an incubator, at the same time being thoroughly mixed, is tested for blood. It will be found that the liquid portion presents but little change in color, while the particles of cracker will be stained deep blue, showing that the hematin granules have become attached to them.

Frequently, when unfiltered contents are examined for occult blood, it will be found that the liquid portion is negative while the mucus is positive. While this, at times, is undoubtedly due to the fact that the mucus has been detached from an eroded or congested mucous membrane, yet I believe it is more often due to the granules of hematin throughout the contents having become adherent to the mucus. The mucus and food particles play the same rôle in the filtration of the gastric contents, as egg albumen in the preparation and filtration of broth cultures.

6. Specimens of gastric contents positive for blood were examined immediately after removal and the intensity of the reaction noted. These were then allowed to stand for three to six hours. At the end of this time the upper, clearer portion and the sediment were examined separately. It was found that the former was either negative or only faintly positive for blood, while the latter gave a stronger reaction than the freshly mixed contents. This is due to the fact that the blood exists in the form of hematin granules, which by reason of their high specific gravity and their tendency to adhere to other particles, rapidly gravitate to the bottom of the glass. This obviously is of considerable practical importance; for if the upper portion of such a specimen is poured off, and employed for the blood test, almost the same negative results will be obtained as with the filtrate.

Certain factors influence the contrast which exists between the filtrate and unfiltered contents. The sooner the filtration after removal and the greater the amount of blood in the unfiltered contents, the less the contrast. The greater the amount of particles in suspension, and the more thorough the process of filtration, the greater the contrast between the filtrate and unfiltered contents in their behavior to occult blood tests.

All these observations have been made sufficiently often to show that they are constant. They show clearly that examinations of the filtrate are unreliable in determining the presence of occult blood in the gastric contents. The mixed unfiltered contents or, if the test is to be more sensitive, the sediment after standing or centrifuging should be employed. This fact is not generally recognized; for in the leading textbooks on gastrointestinal diseases instructions are given to employ the filtrate for the test.

16 EIGHTH AVENUE.

FILING CONVENIENCES SUITABLE FOR PHYSICIANS.

BY J. MADISON TAYLOR, M. D.,
Philadelphia.

The man in active practice has need for convenient and systematic means for filing at least a dozen varieties of data of written or printed materials. Among them are the following: 1. Short notes on cases, on the casual client; to jot down the name, address, complaint and primary advice given. 2. Fuller notes on progressive cases. 3. Associated data, correspondence about cases, etc. 4. Business correspondence. 5. Reprints of medical and scientific papers. 6. Useful data from advertisers, objects, instruments, materials and drugs, especially working bulletins of new products and scientific researches of the manufacturing houses, as advocated by Dr. Francis E. Stewart. 7. Hospitals, sanatoria, special schools for mental defectives, convalescent homes, summer camps for boys and girls and others. 8. Climatic data, reports, transportation, miscellaneous. 9. Small card index for books; a, books in one's own library; b, books desirable to read at some time. Differentiate by colors of cards, or better by colors and separate drawers. It is also desirable that any or all of these reference data should be readily accessible, in reach of his office chair.

In pursuance of an earlier enterprise which impressed me with its importance, I wrote a series of letters to the editor of *Journal of the American Medical Association*, beginning about twenty-five years ago, offering suggestions to the great manufacturing houses, the purveyors of useful objects, drugs and other materials, urging that they adopt a uniformity in the size and shape of their printed matter, in particular that they use the standard three by five inch index filing card, for business summaries, cards or small booklets.

These recommendations were at once adopted by certain manufacturing houses and now most of the large drug firms are following suit. Later I urged that the leading medical journals agree upon a uniform size and shape of their fuller data. So far no attention has been given to the hint. They must come to it; the sooner the better. A recent communication elicited attention from some of the drug houses and I was asked to offer specific recommendations. After consulting the makers of filing cabinets I learn that it is entirely practicable to use certain standard cases. These being adjustable, any one being able to adopt some one or more parts, I offer the following idea.

A filing cabinet of standard qualities can be assembled to contain: 1, one section of five filing cases or drawers, each five by eight inches, horizontally placed; 2, one section, three drawers, nine and a half by ten and five eighths inches vertically placed; 3, one section of five drawers each three by five inches; 4, a stand sixteen inches in height. The whole constitutes a cabinet thirty by sixty inches of handsome appearance.

To this could be added one section of two drawers each eleven by fourteen inches. This would be admirably complete and would well repay

the cost, in time, effort, and worry now expended. The cost of this cabinet would be for the three sections (as first described) about ninety dollars at present prices. Should any one be interested I have sent a manuscript (accepted) to the *Scientific American* describing my own method of arranging and filing scientific data.

The serious difficulty which remains is to induce the medical journals to adopt a uniform size and shape for reprints. And yet in America we boast of our system; of our prompt adoption of all labor saving devices!

These suggestions would meet the current or urgent needs of most practitioners. Should anyone wish to go into the enterprise more completely or comprehensively, the methods of Melville Dewey, of the New York State Library at Albany, might be adopted, wholly or in part. It is called the Decimal Classification or Relative Index, and provides a practically perfect system for classification of data.

1504 PINE STREET.

THE DIAGNOSIS OF CHRONIC CONDITIONS BY THE SPINAL REFLEX SYSTEM.

By ALBERT C. GEYSER, M.D.,
New York.

Correct diagnosis must forever remain the key-stone to proper treatment. Any means or agents capable of furnishing assistance are always welcomed by the physician and appreciated by the patient. Before we can form an opinion as to the use of electricity in determining the underlying cause of any chronic ailment, it will be necessary to review, at least lightly, some anatomical as well as physiological facts.

Entirely too much time is spent and too much stress is laid upon considering the pathology in any given case. Pathology is that branch of medical science which treats of the modifications of function and changes in structure caused by disease. It is always an aftermath. Let us suppose, for the purpose of illustration, that a tornado has passed through a part of the country. Usually an area of a certain width, and frequently miles in length, has been devastated, trees have been uprooted, houses blown from their foundations, fires may have broken out, and perhaps lives lost. After the storm (the disease) is over, those who were lucky enough to escape may view the ruins (the pathology). It may be granted that an expert in such matters may be able to tell us from the damage (pathology) done, just what kind of a storm it was; he may be able to tell us the extreme velocity of the wind as it passed through, as well as the direction from which it came; he may even know just how many such storms have previously occurred in this or some other region, or when another of a similar nature might be anticipated. While all of this is very scientific and interesting, the stricken population (the patient) are more interested in the reconstruction (the physiology) in the rebuilding and possibly in the prevention (prophylaxis) of a recurrence.

So far as the actual damage is concerned, it might

have been worse or it might have been better had it been caused by a conflagration, flood, or earthquake. This does not mean that pathology does not serve a good or useful purpose; but it does mean that, so far as a cure, a return to the normal, is concerned, more time should be spent in the study of physiology. This at least applies more especially to the practising physician. Pathology is always an end result, while physiology enlightens us in the actual reconstruction, in the appreciation of the deviation from the normal and a return to it.

Every chronic disease depends for its continuance upon a greater or lesser deviation from the normal anatomical and physiological makeup of the individual. It is, therefore, apparent that we must not only judge the individual as a whole, but must ever bear in mind the cellular construction of the human body. Each individual is but a conglomeration of cells; as each cell is, so is the individual; he is the cells, the cells are he.

THE CELL DOCTRINE.

Nearly a half century has passed since Virchow, in his *Cellular Pathology*, expressed the idea that each animal appeared as a sum of vital units, each of which exhibited all the characteristics belonging to life. Not only that, but he maintained the thought that each cell sprang from a preceding or parent cell by division, budding or otherwise; he believed that the character and unity of life were referable not to any single locality of a higher organization—for example, the brain of man—but rather to the definite, constantly recurring arrangement which each single element bears to itself.

Taking the correctness of this view for granted, the composition of a large body of the so-called individual must always depend upon a social arrangement; in fact, it represents a social organism in which there is a mass of single existences related to one another in such a way that every element has its own special activity, and each, when excited to activity by other parts, does its work and performs its function of and by itself. If this idea is correct it must apply not only to the body at large, but also to each organ, to the nervous system, even to each cell entering into the composition of any tissue.

During the last few years it has been possible to approach the nervous system with instruments of great precision, with better recorded observations of disease of the nervous system (testing and recording after condenser discharges on injured nerves), aided by the refutation or confirmation of previously existing data, thereby arriving at the newer conception of the neuron as a unit. In fact, the study of the functional units in the nervous system could be approached satisfactorily only after it had been clearly shown that the nervous system, like all other tissues, consisted of elements more or less isolated and independent, and connected directly with one another apparently only by contact, concrescence, or protoplasmic bridges, and after we had learned to recognize the different structures which belonged to the single elements.

THE NERVOUS SYSTEM, CENTRAL AND PERIPHERAL.

In describing the nervous system, for convenience of comprehension we separate the entire system

into two general divisions, yet it must ever be borne in mind that these two portions are anatomically, as well as physiologically, one system. The central nervous system includes the cerebrum, cerebellum, and the pons, or all of that portion enclosed within the cranium proper, while the peripheral portion in-

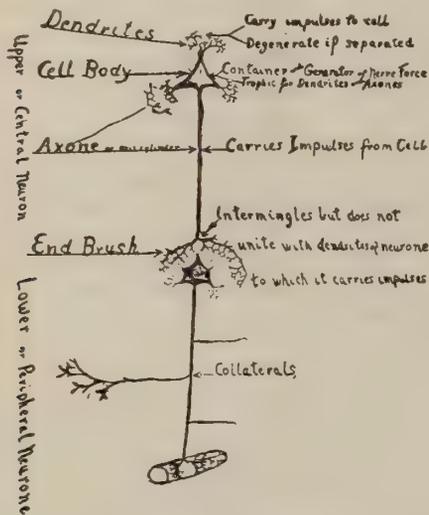

FIG. 1.—The ganglion cell with its dendrons and axis cylinder.

cludes the spinal cord, the nerves, and the sympathetic system. By virtue of its continuity, the nervous system brings into connection all the other systems of the body. Conforming, as it does, in shape to the framework of the body, its branches extend to all parts. These branches form the pathways over which the nerve impulses travel toward the central system, and, in consequence of the impulses received, there pass out from the central system other impulses to the muscles and glands. In order to maintain harmony between the activities of the several systems composing the body, it is at once apparent that the pathways leading to the central nervous system, as well as the paths conducting impulses from the centre to the periphery, must be in a normal state to perform their particular function.

A SHORT REVIEW OF THE ANATOMY OF A NEURON.

By the term neuron we understand the entire mass under the control of a given nucleus forming both the cell body and its branches. The cell body contains the usual granular material with a nucleus and a nucleolus. Nerve cells differ in the number of branches arising from them according to their physiological function. Motor cells possess one principal branch, which, when spoken of alone, is called the nerve fibre, but when considered as the outgrowth of the cell body from which it originated is called the axone. This axone usually has branches, which are designated as collaterals, and the distal ends of the axone divide into finer branches, forming the terminal arborization.

Contrasted with this principal outgrowth are the other branches of the cell, which are, of course, individually much shorter and which divide dichotomously at frequent intervals, forming a treelike appearance; hence their designation dendrites.

An axone in the central system may reach from the cerebral cortex to the lumbar enlargement, while the longest nerve fibre of the peripheral system reaches from the lumbar enlargement to the toe; the longest fibres are found in the spinal ganglia of the lumbar region, where one axone passes to the bulb while another of the same cell passes to the skin of the toes, thus spanning the entire length of the body.

Some of these fibres are medullated, while others are not; most of the nonmedullated fibres are found in the sympathetic system, although a few are present in the cerebrospinal system. The function of this medullary sheath is at best problematical; it has been suggested that this coat acts as an insulation, but there is hardly any warrant for such conclusion. That, however, it may act to the nerve fibre as the periosteum does to the bone appears more probable.

The ganglion cell with its dendrons and the axis cylinder with its terminal fibrils together form an anatomical and physiological unit—a neuron. (Fig. 1.). Every nervous pathway is made up of a series of such neurons communicating with one another. There does not seem to be any direct anatomical continuity in these neurons, which communicate with one another like cog wheels, the terminal fibrils of the axis cylinder of one neuron inserting themselves between the arborizations of the cells of another neuron. The brain, spinal cord, peripheral nerves, and sympathetic system are composed exclusively of neurons of this character and their articulations.

It is thought that the transmission of an impulse is effected from one neuron to another by some protoplasmic prolongation, or contraction and re-

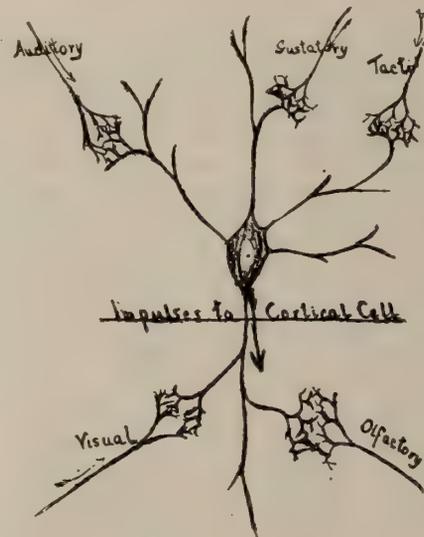

FIG. 2.—Communicating dendrons and collaterals.

laxation, or by some vibratory movements of the terminal filaments. Such impulses are carried to the cells by the axis cylinders. Every neuron probably acts in relation with several others, the most extensive communication being made possible by the innumerable dendrons and collaterals. (Fig. 2.)

A cortical cell may receive a single impression or a number of impressions at one and the same time. These impressions are weighed and may be transmitted to the motor cell of the central neuron. The central motor neuron transmits the desire to the multipolar cell in the gray matter of the anterior horn of the spinal cord. The peripheral motor neuron is then actuated and causes the propagation to the end organ; this may be a muscle, gland, or other tissue, which, when excited into activity, performs its physiological function. It is no fault of a normal tissue that it performs its own physiological function; it cannot do otherwise.

THE PYRAMIDAL TRACT.

Situated in the central convolution of the brain is the motor cortical zone. The cells located in this area form, first, the corona radiata, then, by converging, enter the internal capsule where they are found in the knee and the anterior third of the posterior limb. This portion of the ventral peduncular fibres emerges at the posterior border of the pons in a compact bundle, known as the pyramid, and

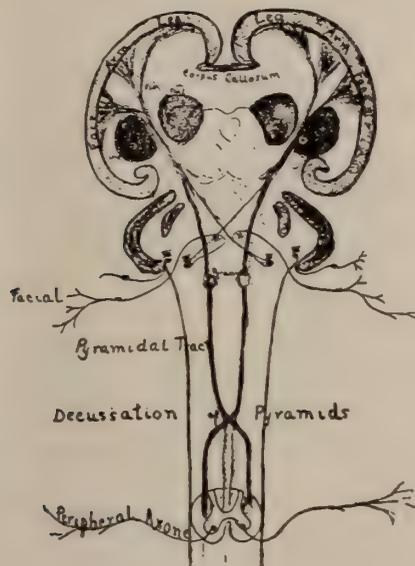

FIG. 3.—The pyramidal tract.

continues its way down the spinal cord as the pyramidal tract. (Fig. 3.)

Most of the fibres undergo decussation and occupy the lateral column, while the smaller, uncrossed portion remains in the anterior column. This tract contains the longest fibres of the corona radiata and can be followed in the lateral column of either side as far down as the conus medullaris. This tract forms the central motor pathway. The axis cylinder, or nerve fibre, of this central tract splits up along various levels of the brain and spinal cord into its terminal fibrils, which surround the dendrons of the ganglion cells of the peripheral motor neuron, located in the various ganglionic enlargements of the spinal cord. The nerve processes of the peripheral cells emerge as nerve roots from the brain and anterior horn of the spinal cord of the same side, and are continued as motor fibres to the muscle, where they finally break up into their ter-

minial fibrils among the individual muscle fibres (end organs). The central motor neuron, therefore, undergoes decussation, while the peripheral does not.

The impulses which originate in the cells of the cortex are transmitted to the muscle through the pathway formed by these two neurons, and from the decussation of the central neurons it follows that the cortex of each hemisphere controls the muscles of the opposite side of the body. In apoplexy the lesion occurs upon one side of the cerebral hemisphere, while the muscular paralysis, owing to the decussation of the central motor fibres, presents itself upon the opposite side of the body. On the other hand, in poliomyelitis, the multipolar cell in the anterior horn of the spinal cord is involved. It is at this point that the central neuron ends, while the peripheral begins. Since the peripheral motor neuron does not decussate, it follows that the muscle paralysis must occur upon the same side as the lesion in the spinal cord. In cerebral apoplexy the blood clot presses upon some portion of the motor cortical zone or upon some of the axis cylinders in the capsule, hence the will or the desire for muscular contraction cannot be transmitted to the multipolar cells in the cord. This lack of impulse transmission causes the paralysis. Since the affected muscles are in anatomical and physiological contact with their trophic centre there is not only no wasting nor atrophy, but there may be a spastic paralysis in addition, instead of a flaccid paralysis. In poliomyelitis the axis cylinder, the end plates, and the muscles are separated from their trophic centre; hence there is complete flaccid paralysis, as well as early atrophy. The atrophy in cerebral hemorrhage is gradual, the result of nonuse; the atrophy in poliomyelitis is due to the loss of the nerve or centre of nutritional control—secondarily to the nonuse.

Every neuron cell exercises a trophic influence on its processes, including the long axis cylinder process, the end organs, and the tissues which it supplies. If this influence is destroyed, the corresponding nerve fibre undergoes degeneration, and the ganglion cell itself suffers degenerative changes if the continuity of the neuron is for a long time interrupted.

THE SENSORY PATHWAY.

The function of the sensory pathway is to conduct sensory impressions from the periphery to the centre. The peripheral sensory neuron complex of the extremities and trunk is contained in the sensory fibres of the peripheral nerves. From its various distributions to the skin and other parts, it continues its course to the spine through the fibres of the various plexuses, and ends in the cells of the spinal ganglia, without directly entering the spinal cord. (Fig. 4.)

The cells in the spinal ganglia differ from other cells in that they possess two axones, giving the appearance of the fibre entering at one end of the cell and leaving at the other; these fibres, by which the nerve leaves the cell in the spinal ganglia, collectively form the posterior root, and, as such, the sensory peripheral neuron finally reaches the spinal marrow, the posterior roots entering in two separate parts

into the posterior columns that lie between the posterior horns. After its entrance into the spinal cord, each root fibre divides into an ascending and a descending branch, and these branches soon divide to communicate with the cells in the gray matter of the spinal cord, as well as sending collateral branches

fore the cortex of the cerebrum is put into communication with the periphery.

THE REFLEXES.

By a reflex action, we mean a motor act performed automatically in response to a sensory impression. The entire act is confined to the peripheral neurons, which, therefore, form the reflex arc (Fig. 6). This reflex arc is composed of a sensory portion contributed by the peripheral sensory neuron, a motor portion contributed by the motor peripheral neuron, and a connecting link formed by a branch of the sensory neuron after its entrance into the spinal cord; the last is known as the reflex collateral. The course of the cutaneous and tendon reflex arc is better known than that of any of the others. We distinguish a short and a long reflex arc. The short reflex arc consists of a collateral which passes directly from the posterior column through the posterior horn to the cell in the anterior horn; under this head are included the plantar and spinal reflexes. The long reflex arc is formed by the reflex collateral splitting up about a cell in the anterior horn; from this cell an ascend-

FIG. 4.—The sensory pathway.

upward into the posterior columns, where are located fibres controlling tactile sense and muscular coordination. These fibres pass upward through the entire length of the spinal cord, and finally break up surrounding cells in the nucleus of Burdach and Goll, located in the medulla oblongata. The terminal divisions of the peripheral sensory neurons take place about the nerve cells lying in the following regions (Fig. 5): First, in Goll's and Burdach's nuclei in the medulla; second, in the various portions of the posterior horns; third, in the middle zone between the anterior and the posterior horns; fourth, in the columns of Clark; fifth, in the anterior horn.

The central sensory neuron complex begins at the ending of the peripheral neuron in the regions mentioned in the first four above noted distributions. These fibres, which enter the posterior root zone and communicate with cells situated in the anterior horns (noted fifth above) are especially concerned

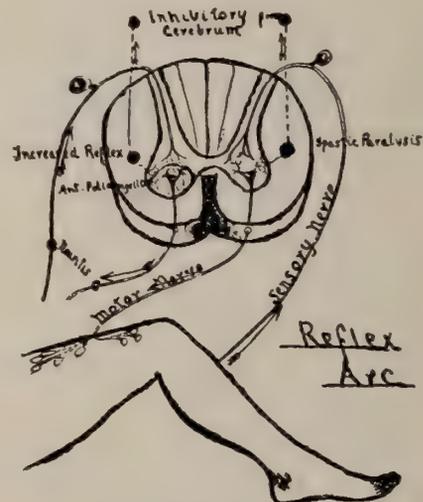

FIG. 6.—The reflex arc.

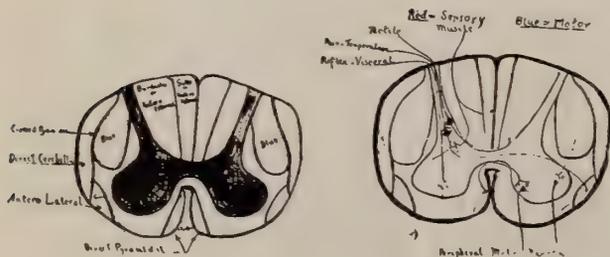

FIG. 5.—The terminal divisions of the peripheral sensory neurons.

in reflex action. Up to this point the distribution is fairly well settled, but the further course of the central sensory tract is still a matter of dispute. By some authorities it is maintained that, after the central sensory neurons reach the medulla oblongata, one, two, and even more neurons, are required be-

ing and a descending branch, with several collaterals, pass to one or more motor ganglion cells, which may be situated at various levels of the anterior horn. This gives the possibility of reflex movements being transmitted to more remote muscle groups.

Of the more complicated reflex arcs we have little definite knowledge, as the pharyngeal, nasal, bronchial, conjunctival, pupillary, and others. There are, however, a few of the more important reflexes that should not go unnoticed. Locomotor ataxia, for instance, even in the beginning, may be diagnosed by the absence of the patellar reflex, the absence of the pupillary reflex, and the swaying of the body with the eyes closed; here, then, we have three reflex arcs, any one of which should cause a further investigation, while the presence of any two of these would strongly point to an assured diagnosis of tabes dorsalis.

In order to elicit the presence or absence of the knee jerk, the patient should be placed in a sitting posture, on a high stool, so that both legs are free

and not resting upon anything; the patient should then be instructed to link his hands together, close his eyes, and to exert a strong pulling force with both hands the moment that he feels the blow struck upon his patellar tendon; this, of course, simply assists in diverting the patient's attention from himself, and all undue strain or tension is thereby removed from his lower extremities; it is also well to bear in mind that, with some normal individuals, the knee jerk is absent. This absence of the knee jerk was first described by Westphal, hence its name, the Westphal sign.

The Argyll-Robertson pupil is a loss to accommodation to light, but not to distance. It may be obtained best in a dark room by suddenly flashing a small electric light, when a contraction of the pupil should occur; the absence of this contraction furnishes a valuable reflex diagnostic sign.

The Romberg symptom is usually present early in locomotor ataxia and is due to loss of muscular coordination. Place the patient in a standing position with his heels and toes together, body erect, order him to close his eyes, and very shortly a marked swaying of his body will be observed. This swaying may become so intense that the patient must be guarded lest he fall. The Achilles reflex in some cases of locomotor ataxia, as well as in paresis, is sometimes absent even earlier than either of the previous ones.

In lesions of the peripheral nervous system we have, then, generally speaking, a loss of reflex action, while in disease of central origin we expect to be assisted by an undue increase of these reflex phenomena.

INCREASED REFLEXES

The patellar reflex may be markedly increased; the increased reflex act, however, is best shown by the ankle clonus, especially if clonus is present. Take the heel of the patient in the palm of the hand and with the other hand make sudden pressure upon the ball of the patient's foot so as to cause a strong flexion of the foot; as long as this flexion is maintained the ankle clonus, if present, will be manifested. Such an increased action, then, would indicate a lesion of central origin, with possible secondary changes in the pyramidal tract, as in lateral multiple sclerosis, or as the result of apoplexy.

The cutaneous, or superficial, reflexes are not so well understood; attention should, however, be directed to the Babinski phenomenon. Under normal conditions, if the sole of the foot be irritated, excepting in very young infants, there is a flexion of all the toes, but in diseases of the pyramidal tract or apoplexy, when the sole of the foot is gently irritated, there is a gradual extension of the big toe, sometimes of all the toes; this becomes, therefore, a valuable reflex sign in cases of coma, for if present it will be pathognomonic of cerebral apoplexy.

SPINAL REFLEX DIAGNOSIS.

Last, but by no means least, is a condition of the sympathetic system along the entire length of the spinal column. During the past ten years I have examined over a thousand spines for this sign, for I know of no other means or symptoms capable of furnishing such unerring evidence of disease as the

spinal sympathetic system. No matter how recently an injury has taken place, no matter how long ago or how obscure the symptom of a chronic ailment may be, as long as some portion or organ of the economy suffers, a reflex centre corresponding to that portion or organ will surely be found somewhere in the spinal cord. Some of these spinal centres are well known; others are more or less obscure. The sense of sympathetic painful areas, however, comes to our aid, though in eliciting pain we are obliged to rely upon the statements of a patient who may be nervous and whose sense of pain may be perverted and, therefore, misleading. Fortunately, I am able to call your attention to a system that will at once commend itself to you for its simplicity as well as for its accuracy.

A correct diagnosis usually narrows the treatment down to a very few agents, and it is merely a matter of expedience which particular method of therapeutics we employ in any given case. Admitting for the sake of argument that it was difficult, nay, even impossible, to arrive at a correct diagnosis during the acute stage of the disease; what, then, are our chances during the chronic stage? Again, we must bear in mind that the patient during the chronic stage is no longer suffering from the acute disease; but rather from some changes that have taken place in the economy, as the result of the acute condition. In other words, the symptoms have entirely changed. Hence we speak of symptomatic treatment, meaning thereby the amelioration of the various symptoms as they may be complained of by the patient. If we give this so-called symptomatic treatment a passing notice, we must admit the absurdity of it and our inability to do better. Here we have a patient whose whole system has been more or less changed by the processes of disease and repair, whose manifestations and interpretations are anything but normal. Let us take, for instance, the neurasthenic, the hysteric, and the hypochondriac. If we were to administer treatment according to the interpretations of their feelings, our already overcrowded therapeutic armamentarium would certainly be inadequate and our results even more chaotic than they are now. In refutation it might be said that these three conditions are not truly disease conditions, but rather psychic conditions; let us bear in mind that the man or woman who thinks he or she is sick, and is not, is sick indeed.

I venture to say there is not a single symptom or manifestation of disease without some underlying cause. The first step in therapeutics is to remove the cause, for no matter how often or how much we may treat the symptoms, unless the underlying cause is removed, the same symptoms must again appear, though changed through the administration of our symptomatic treatment. It is the cause of the symptoms, and not the symptoms themselves, that require our attention. To make it more clear, let us suppose a patient complaining of nothing more than a headache, which may be due to toxemia from intestinal origin, derangement of the gastric functions, changes in the circulatory system, changes in the kidneys, defects of the visual apparatus, frontal sinus disease, nasal or middle ear lesions, uterine lesions, intra-

cranial tumors, congestion or anemia of the brain or its coverings, syphilitic changes, constipation, and a host of psychological impressions. Certainly, with even a slight thought upon the subject, we must become convinced that a cause must be discovered and removed before any real benefit can be expected from our therapeutic applications.

As has been stated, in chronic diseases we are more often suffering from some obscure cause and the symptom complex is frequently referable to some undiscovered lesion bringing forth rather reflex manifestations than directly associated conditions. Pain is an expression of some interference with a sensory nerve, central or peripheral. Without the intervention of a nerve of sensation there could be no sensory impression. Paralysis, or motor inability, necessitates the interference with the function of a motor nerve, either the nerve itself centrally or peripherally, or joint and muscle changes preventing the motor nerve from carrying out its physiological function.

Changes in tissues or organs in general are presided over, not by the sensory or the motor nerves, but by that third system of nerves, the sympathetic. All growth and repair of tissue is under the direct control of the sympathetic system. All injuries, traumatic, chemical, or biological, aside from the pain, loss or increase of motion, are under the direct influence of the sympathetic nervous system. It is this system that takes cognizance of the changes which have taken place and, under its control through the vasoconstrictors and dilators, the process of repair is more or less perfectly carried out.

THE AUTONOMIC OR SYMPATHETIC SYSTEM.

For our purpose and for the sake of brevity we will make no special distinction between the sympathetic proper, the bulbar, and the sacral subdivisions. Neither is it advisable to consider in too much detail the anatomy of this system, but only so much of it as is really necessary for the elucidation of the problem of spinal reflex diagnosis. The sympathetic nervous system is intimately connected with the cerebrospinal system, though it differs from it in many ways, especially in its peripheral distribution.

The sympathetic system consists of a highly complex arrangement of ganglia, nerve fibres and nerve plexuses, which are distributed to the different regions of the body. Especially does this peripheral distribution hold good for the blood vessels. Wherever blood flows, there is found a sympathetic nerve to control the same. The largest blood vessel, as well as the smallest capillary tube, has its own sympathetic fibre. In its minute structure the sympathetic system presents the same general constituent elements as the rest of the nervous system, viz., nerve fibres, ganglion cells, and a complicated fibrillary network around the ganglion cells which probably originates in the processes of the nerve fibres. The single nerve fibres unite into nerve trunks, while the ganglion cells and the network of fibrils accumulate at certain points along their course.

THE SYMPATHETIC AND VASOMOTOR SYSTEM.

Beginning with the Gasserian and otic ganglia within the cranium we have placed upon the ante-

rior and lateral aspects of the spinal column a chain of similar glands. In the cervical region we find three ganglia, the superior, the middle, and the inferior cervical, while below this region there is placed one ganglion corresponding to each of the vertebræ. These two chains of ganglia are connected so as to unite in the lowest ganglion, the ganglion impar. From each one of these ganglia fibres are given off to pass into the cerebrospinal column through the nervi rami communicants. Other fibres are given off at various levels of the spinal cord to follow the course of the blood vessels, and in this way the sympathetic nervous system is brought into close contact with every single part of the body. In fact, each individual cell is under the direct influence and control of this system.

If, then, a single cell within the body were to receive even the slightest injury, it would become the duty of this system at once to recognize such injury and, by sending some sort of stimulus to the corresponding ganglion of the cord, start the process of repair either by limiting, or, as is more likely to be the case, to increase the local blood supply to this part.

Each organ within the body has located somewhere along the spinal column one or more of these sympathetic ganglia which neither rest nor sleep, but continually, like faithful sentinels, attend to the least beck and call of the particular region or organ with which they are connected. Let us suppose for a moment that something has gone wrong with the stomach; then the ganglia located at the third, fourth, fifth, sixth, and seventh dorsal vertebræ would at once be made aware of such an injury and within these ganglia all would be excitement; much as though some fire station should receive a hurry call or to hold itself in readiness to give assistance at the next tap of the bell. Let us carry our imaginary excitement a little further by assuming that the call bell has struck, again and again, yet with all the available force working, the apparatus can not be moved an inch; the call bell keeps on ringing; the men, frantic at their work, now gradually cease and drop from sheer exhaustion; no help has been sent and the destruction by fire goes on. So in our sympathetic ganglia; if the injury is great enough or repeated sufficiently often, these ganglia, after a valiant effort, are obliged to refuse, in order to save themselves from utter destruction. Such stations along the spine are known as sympathetic spinal centres. Many of these centres are well known, as the centre for respiration, the centre for cardiac activity, the centre for the liver, large and small intestines, the centre for parturition, micturition and defecation.

During the last few years, laboratory and clinical data have enabled us to locate more or less definitely nearly all the various centres along the spine. In the first part of this paper we saw that this sympathetic nervous system sent its branches wherever blood flows; it so happens that a branch of these ganglia controls the blood supply to the skin immediately overlying the region of the particular ganglion in question. That is to say, if we are dealing with a lesion of the stomach, for instance, the pyloric end of the stomach, then the area over the

fourth and fifth dorsal vertebræ would be supplied by a branch of the sympathetic from the ganglion, because the ganglion located here controls the pyloric end of the stomach. Would it seem very far-fetched if, in carcinoma of the pyloric end, or any other chronic lesion at this region, we should also find some small involvement of the region surrounding the centre along the spine? We know that this does happen. I can do no better than refer to any one of the modern textbooks on diagnosis, where complete charts will be found giving locations of painful areas along the spine associated with various internal disorders.

In its distribution along the spine, the entire sympathetic system may be divided into three main divisions, viz., the cervical brain, extending from the atlas to the fifth cervical vertebra; the abdominal brain, extending from the first dorsal to the second lumbar; the pelvic brain, extending from the ninth dorsal to the fifth lumbar. While these divisions are only arbitrary, they nevertheless serve as a guide to the distribution of the main plexi and the particular area they control. In order to appreciate more thoroughly the diagnosis of chronic ailments, it will be necessary to keep in mind the fact that we may, and usually do, have symptoms in some organ, yet that organ is perfectly healthy and so requires no therapeutics; it is simply a reflex symptom. A gravid uterus may cause uncontrollable emesis; the gastric organ is not at fault, yet the vomiting is the only symptom of which the patient complains. Intestinal parasites may cause convulsions, yet no physical signs of the worms may be present; in fact, nothing seems to point to the intestines at all as the possible site of the trouble. Ocular defects have been known to be the only cause for epilepsy, yet have never been suspected. Lumbago, a frequent condition during stone in the kidney or bladder; yet there may be nothing wrong with the lumbar region itself. Headache, due to some gastric disturbance, hemorrhoids and constipation furnish reflex symptoms too varied and too numerous to mention. This array serves once more to impress the necessity of locating and treating the cause and not the apparent symptoms.

HOW TO LOCATE THE CAUSE.

We thoroughly appreciate the fact that every organ in the body is controlled by the sympathetic nervous system, and that this system has located near the spinal vertebræ certain ganglia; that these ganglia act as substations or centres from which impulses are sent out. We also appreciate the fact that the overlying skin area surrounding these centres shares in the immediate condition of the centres themselves. If, then, any one organ in the body is abnormal, the corresponding centre must also be abnormal. Now it is simpler to find the abnormal spinal centre *per se* than to find the abnormal organ *per se*. Knowing the centre we can easily locate the organ supplied by that centre and so find the underlying cause for the particular ailment.

APPARATUS NECESSARY.

Procure a high tension faradic coil with not less than five thousand feet in the secondary winding; personally, I never use less than seven thousand feet,

and lately I had built for me a coil with eight thousand feet of especially fine wire, and two interrupters in the primary. Why do I use such a length of fine wire, and why two, instead of the usual one interrupter, in the primary? The greater the number of secondary turns surrounding the primary of a faradic coil, the oftener are the lines of force cut and, therefore, the greater the tension, or the penetrative power, of the secondary current. The fine wire is used instead of the coarse so as to make the distance between the centre of the coil and the periphery, or the last layer of winding, as short as possible. The more rapidly the current is interrupted the less the sensation to the sensory nerves, and so this kind of current may be used to its fullest extent without practically any sensation or muscular contraction to the patient. For these reasons the error should not be made of using a short coil, for it cannot produce the desired penetrative power nor the necessary interruptions, but instead it may cause severe muscular contractions of a decidedly painful quality.

A muscle will respond to individual stimuli up to about thirty a second. As muscular contractions and relaxations require time for their performance, when the rate of interruption is higher than thirty a second, there is not enough time for complete relaxation and the muscle assumes a condition of tetanus. This tetanic condition becomes more and more manifest as the oscillations increase in frequency, until they reach about three thousand a second, and is stationary or at its maximum up to five thousand a second. If the rate of vibrations is still further increased, the muscle gradually returns to a flaccid condition because it can no longer respond; it no longer appreciates the stimulus; consequently, there is no muscular reaction.

TECHNIC.

The patient is placed in the horizontal posture upon the examination chair or couch; the spine is uppermost and bared. A large felt electrode, not less than six by eight inches square, properly moistened, is placed just above the umbilicus so as to cover the abdominal brain or solar plexus. This pad is attached to the positive end of the coil, while the negative end is attached to an ordinary sponge hand electrode, not over two inches square. This examining electrode should be fitted with an interrupting device.

The current is now turned on from the full length of the winding to about one half of its possible strength and the sponge brought in contact with the cervical region of the patient. The interrupting device is released and the current flows. The patient is now consulted as to the feeling of the current, which must be in no wise disagreeable. If everything is working satisfactorily, the electrode is gently moved up and down the entire length of the spine six to eight times, with moderate pressure only. The patient should now tell the examiner if the current is felt more in one spot than in another. If it is not felt anywhere in particular or everywhere alike, increase the current and proceed as before. If the patient shows by wincing that there are some tender spots, mark these spots with an indelible pencil.

The current may now be stopped and, to our surprise, just where the patient complained of feeling the current, there appeared bright red areas from the size of a twenty-five cent piece to the size of the palm of the hand.

These spots stand out in bold relief upon an otherwise white background. This phenomenon must have a cause and we must account for its occurrence. Immediately underneath this red area are located spinal centres which, perhaps, have been for a long time laboring under great stress from the impulses sent there from some abnormal organ. Now, when this hypersensitive area is irritated with the proper kind of current, it will respond by an increase in the local blood supply long before the rest of the skin along the spine is even aware of the presence of the irritant. By looking at our chart we find which particular part of the body or which organ is associated with the responsive centre, and so locate the abnormal or diseased organ which is responsible for the hypersensitiveness of the sympathetic area just tested.

Once having located the organ or region it is not very difficult by a process of exclusion to arrive at the correct diagnosis.

ANEMIC AREAS.

Besides the red spots just mentioned, every once in a while it happens that a certain sharply circumscribed area will suddenly become blanched. Such areas are of the same general contour as the red spots. There is no doubt that, in my earlier tests, many of these anemic spots escaped my observation, yet when once seen, thereafter, when one is on the lookout for them, they appear almost as plain as the hyperemic areas. At this writing I am not able to give a very satisfactory explanation as to their true significance.

Since the red spots apparently reflect a condition of hyperexcitability in the ganglion from some irritation from a distant organ, is it not also possible that these anemic spots portray the true condition when the opposite state exists? Let us suppose that an organ like the kidney is in an anemic state, the small fibrous contracted kidney; then, if the ganglion has long since given up the attempt to produce any change or repair, the ganglion itself would be in a more or less anemic state; it would then reflect its own condition through the blood supply in the overlying skin area, hence the anemic or blanched spots. It is, however, purely speculative on my part at this time to venture these suggestions.

Just a word about such diseases as hysteria and neurasthenia. It seems as though two such diseases ought to be differentiated easily, but as a matter of fact they are not, especially when the main symptoms of either are more or less present or absent in the same individual. How will a spinal diagnosis help us, then? Simple enough, if one stops to think before proceeding with the mechanical part of the work. Neurasthenia is, as the name implies, an asthenic condition of the nervous system due to debility or weakness of the nerve-centres, not in any one particular spot, but a general exhaustion. When the sympathetic nervous system has for a long time taken notice of such a condition, it is ready to respond to almost any kind of stimulation or irri-

tation, and thus, in neurasthenia, the entire length of the spine will present one long red streak. In this instance the neurasthenic patient and his spine are in absolute harmony. Such patients respond to every new kind of a therapeutic procedure for a time; they are the ones who constantly supply the sinews of war to the ever new, and more or less fantastic, therapeutic measures brought to their attention.

If the examination is made with extreme caution we will frequently be able to locate the underlying causes by watching the manner or order in which the various portions of the spine turn red. In every case of neurasthenia there is an underlying cause; it is not always easy to detect it, but it is there.

In hysteria we have the opposite condition; a more or less perverted state of the mind due in most instances to some slight underlying physical cause. When a spinal examination is made, hardly a single spot or reaction is seen, even after prolonged irritation, because the psychical element predominates over the physical. Neither does such a patient complain of the strength of the current; in fact, as a rule, the stronger the current the better he seems to like it. But even here, if a reaction does appear it is very insignificant, out of all proportion to the gravity of the symptoms as complained of by the patient. Nevertheless, we again are frequently led to the source of this disease.

I do not wish to convey the impression that this method of diagnosing disease is in any way a substitute for other methods; on the contrary, in locating the organ at fault all the other methods must be brought to bear, until, by a process of elimination, the final and true pathological status becomes known. Perfect and valuable as this system of reflex diagnosis may be, it merely locates the seat of the trouble, leaving us to find out the rest; it does not tell us what the trouble is.

301 WEST NINETY-FIRST STREET.

HEREDITY.

BY L. DONALD McEVOY, M. D.,
New York.

THE NEURAL CONTROL.

It has been indicated how the fixed principles of natural law necessitate the perpetuation of a cell type indefinitely, irrespective of the effects of environment or natural selection: how the proliferation of a cell into a mass (or zone) carries within the zone evidences of a limiting power analogous to that giving form and shape to a crystal: how groups of heterogeneous proliferating cells held together by chemical affinity, will upon proliferation form bodies, and how the necessity of coordination and function between the zones of a body, require the establishment of a mechanism of balance and what was termed a neural control.

The combination of elements forming a cell whose functions are limited to intake, output, and proliferation, would obviously require little control other than that furnished by the chemical valencies of its elements. When, however, a group of heterogeneous

cells, each bearing the potential of a zone, proliferates to form a body, then the complexity of a body is in direct ratio with its number of zones. Its neural control will be correspondingly complex, approaching infinity in the number of its possible variations. The addition of special senses, mechanisms to accommodate environment, and its motility—one and all add their quota to the bewildering labyrinth of neural activities as impalpable, intangible and undefinable as electricity, yet obviously as quantitatively and qualitatively dependent upon chemical reactions.

THE INSTINCT OF POSSESSION.

The zone is the unit of structure. It as a unit develops, matures and reproduces its kind. It may mature earlier or later, may be weaker or stronger, yet as one of a communal group it is dependent upon the action of the neural control. A zone therefore has no method of escaping the responsibilities of its position. Its desires must be transmitted to the neural control, compliance with which would mean the activation of all the mechanisms of the body. Thus a deficit of chemical elements transmitted by a zone would produce hunger in the neural control. To appease it the huge complex of the body mechanism must be set in motion. To satisfy the zone the muscles of volition move the legs, the arms, the jaws. The mechanism of digestion prepares to disintegrate the food into the elements suitable for all its zones, and the distributing channels dispose of it impartially—to the zone complaining—but also to the others. If the environment is unfavorable and the food difficult to secure, the action becomes more complex. The special senses are called upon. They register impressions which are referred to memory cells. If memory fails to recall experience, a process of reasoning must ensue, and the experiment of edibility tried, controlled in a measure by the chemical repulsions indicated by odor and taste. If an object known to be edible is in possession of another, offensive measures may be tried, or, if this fails, methods of deception used.

In either case, the origin of a habit can be observed, forming within the neural control of considering the desirability of objects—a sense of ownership regarding them. It should be clear that an environment whose aspect was harsh and forbidding would more readily produce such an effect than one offering a profusion of edible substances.

It is of importance that the relation between the chemical wants of the zones and the resulting effect upon the neural control be clearly understood, as, though applicable to all forms of life, it will be especially significant when the gestational phenomena of woman is considered. The sense of ownership is the natural corollary of the struggle to live, following as it does the ordinary process of growth entailing the constant supply of elements. It is, therefore, a primal impulse or instinct, and for want of a better designation it can be termed "The instinct of possession."

When the quantitative nature of this instinct is shown to follow the influence of environment, its great potential in the economic life of man and con-

sequent bearing on the subject of heredity will be apparent. It is undeniable that the constant use of offensive mechanisms to obtain food might develop a ferocity of great and unreasoning power, might even produce an unbalance in the neural control changing an appetite omnivorous in nature, into one purely carnivorous, but the ferocity which resented the presence of another, to say nothing of questioning its claims, would produce nothing more than a consciousness of self—an ego—with but rudimentary impulses of possession.

If, however, an ovum is fecundated and its zones proliferate within the uterus of a woman, it is obvious that its growth will depend upon the mechanisms of her body. Moreover, every zone in her body being a chemical analogue or replica of those in process of proliferation within her uterus, will have added to its normal demands for food the requirements of the fetus. The result will be that every energy of her neural control is constantly directed in its dual capacity of sustaining two or more groups of zones. To this responsibility for the proliferating zones is added the necessity of securing protection for them. Thus the female becomes peculiarly susceptible to environment and anything remotely suggesting protection received through her special senses will exert enormous influence.

The driving impulses of hunger transmitted from her zones and of the body of the fetus will, after the delivery of her progeny, culminate in the development of the great primal instinct of possession, modified by the attending protective impulse, producing that most wonderful of emotions—the mother love. In the transmission of this instinct, the factors of its production are active, carrying its potential from generation to generation through the zonal nuclei. Thus habits will be formed, as each body, depending as the case may be upon one or more of its special senses, will perpetuate the custom of selecting certain foods, raising its progeny or adopting a mode of life, thereby increasing the scope of judgment of the neural control.

It will be observed that the possessive instinct differs in its manifestation. In the female it is protective and self-sacrificing, while in the male it is essentially selfish. This selfishness produces end results of remarkable significance. Thus a perfectly coordinating body, having by its ruthless power secured the food or necessities of others in a group, becomes a menace, driving them to the use of cunning. Complex judgments have to be formed resulting in group action to enforce the right of the individual. Here then would be established a precedent, the glimmering of the recognition of the law of ownership as applied to the entire group.

Custom will establish the precedent by which the group profited, which in turn will react upon the neural control of the strongest in an effort to establish his precedence. In all the complex, the neural control is activated and driven by the same impulse unmodified, brutal and ruthless. It is the personification of the law of survival whether exemplified by strength or cunning, in the group or in the individual—the possessive instinct of the male.

THE INSTINCT OF SEX.

When a zone matures it extrudes nucleii, which are carried to the ovary or testicle, there to await the action of the body. One zone may mature before another. In this event the zone may seek to readjust the relative importance of its position in its communal group and as a consequence cause an unbalance in the neural control. Thus vague and unformed sexual manifestations often appear before puberty, due to the maturity of one or more zones, the degree being in direct ratio to the number of zones maturing and the unbalance differing as the control is more or less influenced by their chemical activation. When the body matures (all the zones) the tremendous power exerted by the combined forces demanding the extrusion of their nucleii, may even counterbalance the influence of the instinct of possession, depriving the neural control of its power to reason and producing as a consequence varying degrees of incoordination.

However, the result of one zone maturing or the whole group is always conducive to unbalance of a greater or less degree, but fortunately, as in the adjustment of the special senses to coordination, the regularity of zonal impulses produced habits, so in the adjustment of sexual elements, the habit of functioning at regular intervals is caused by quantitative changes. The extrusion of nucleii by a zone depending as it does upon the zone's virility, and the latter in turn depending upon the amount of food furnished, would inhibit excessive proliferation under normal conditions.

(As an interpellation and with apologies it is thought advisable to mention the possible rôle played by the zonal nucleii in the production of malignant growths. The fact that Cohnheim made a suggestion connecting embryonic elements was the result of the observation of their behavior. The fact that such growths are influenced by the same destructive agency inimical to ovi and spermatozoon as to cancer, is striking, especially so when it is recalled that no known agency capable of destroying the fecundated ovum in utero without injuring the mother, exists. It can be expelled but not destroyed—except by radium.)

Resuming the consideration of the impulses essential to the perpetuation of life forms, we find that in the manner detailed is thus thrust upon the body, the second great quantitative instinct as a factor in the phenomena of the life of a mature body—the instinct of sex.

Like the instinct of possession it is quantitative, varying in direct ratio with the activity of zonal reproduction. It is unlike, however, in the period of its activity. The instinct of possession persists in varying degrees throughout the life of the body, while the instinct of sex, as the zones one by one cease to proliferate, become ineffective and nugatory. Thus a period of greater or lesser length may transpire between the end of sexual activity and the dissolution of the body, in which the neural control ceases to be influenced by the impulse of sex. Here, then, is a period of varying length of time wherein the neural control retaining memory, capable of observing and registering impressions, is not under the driving zonal impulse. The calls

for food are perfunctory, the zones are quiescent, the neural control is left to dream on its memory pictures.

We have, then, two governing factors, the one resulting from the chemical needs of the body structure, the other from the requirements of the law of proliferation, the one arising from deficit and the other from a surplus. And yet a third appears, a factor which intrudes itself with intangible persistence and unknown potential. It is the neural control itself with the suggestive power of its dreams formed when bereft of its impulses, an ego without responsibility, capable of forming thought.

SPECIAL SENSES.

Reference has been made to the special senses acting as aids to the neural control and the mechanisms of the body. The recognition of but five may be due to our exceedingly limited powers of observation, or to the fact that the present environment of man has not called into use the full potential of his structure. We know of curious phenomena regarding thought transference in what has been termed telepathy, of strange gifts regarding the multiplication of numbers, of complex vague phenomena relating to unknown conditions and suggesting the bewildering possibility of projecting without the body, an unknown entity, but whether this, if possible, would be a special sense, an aid to the control, or the neural control itself is a question. Fantastic as the notion may be, it must be met with an open mind. It is probable that as the neural control accommodates itself to new environment it seeks to make use of a potential of which nothing is known, and that such phenomena are nothing more than manifestations of a special sense, as yet undeveloped because of lack of use.

The donated elements forming the neural control are received from the zones, leaving them connecting filaments to transmit their desires. Individually, the zones have no use for special senses other than the tactile, and in this the economy of Nature may limit an allotment, or distribute it over many zones through the medium of their covering. If the connecting filament is broken, the zone is cut off from its neural control. It wastes away, not being able to transmit its wants, and it is doubtful that it proliferates, as a starving body ceases to proliferate, becoming sterile if the degree of starvation is extreme. If the connecting filaments have been incompletely severed, the attention of the control can be called to the trouble and the body mechanisms of repair activated.

The ability of a zone to transmit its desires gives it protection, as it then comes under the supervision of the control. This may explain the so-called faith or miraculous cures wherein the concentration of the neural control has been centred upon one or more zones, with the result that the complaining zones secure relief, if within the power of the body mechanism to give it.

Thus tactile sensibility might be considered the essential of the group of special senses. To what degree of acuteness it might be trained would be difficult to determine, but that it has a profound connection with the neural control should be obvi-

ous. It serves the body in many capacities and it would reasonably hold a place of great importance.

The hand as the principal factor using the tactile sense would therefore be worth observing. When the palm of an infant is touched, it closes its fingers. When the palm of an infant ape is touched it does not grip except perfunctorily. The grip of an imbecile corresponds to that of the ape. The idiot does not close its fingers. Beginning then with the idiot we can ascend the scale of mental development and it would seem to correspond to the reflex of the sensory nerves of the hand. When therefore the palmar reflex of an infant at birth is weak and ineffectual, the existence of an unbalance in its neural control can be suspected, in the same manner that the reflex of Babinski is elicited in certain lesions of the brain.

Every zone in the body has an interest in the ability of the hand to function, its potential therefore should be correspondingly great, and that superstition and ignorance may have deduced great numbers of foolish inferences, should not rob us of the real significance of its indices. The infinite variation of the whorls and deltas observed in finger prints must have their significance, as well as the shape, motility and ability to coordinate.

Thus a perfect hand would suggest a normal zonal alignment if coupled with normal sensibility and power of coordination; the inference could be drawn that no unbalance existed in the control. If variation from normal was found, and the hand could be identified as ancestral, the unbalance, if any, might be traced. However, the tactile sensibilities are rarely acute. Many errors of judgment follow their transmission to the neural control, yet the errors made are relatively few when compared to the number following the transmission of visual impressions. The complexity of the latter mechanism involves so many adjustments that this is to be expected, nevertheless, such judgments (faulty or accurate) as are made, are more lasting than those attributable to other special senses. They may be modified by the discovery of the error, but the unreliability of visual transmissions will have impressed the neural control. A state of indecision is produced. Judgment is held in abeyance, and the inability or refusal to decide forms a habit, thereby increasing the amenability to suggestion.

Thus a mass of individuals may be swayed by suggestion and accept the preformed judgment suggested. It is the dominating factor of the group, and may influence habits in the matter of food and gestation to such a degree that an unbalance may ensue. However, the same factors working for unbalance could be directed to constructive and beneficial ends, as the receptive potential is the same. Plasticity of group consciousness is an essential to the coordination of the group.

That interpretations of visual impressions may be used as suggestions, and are transmitted as received through the auditory apparatus, would indicate that the auditory, like the sensory, is reliable in its transmissions. Its faults are more prone to be those of omission than distortion. It must not be inferred from this that the auditory transmissions have little influence except as they

may be used for the purpose of suggestion. The fact that the position of the tympanum may alter its functional ability to transmit, indicates that as in the visual mechanism, the necessity of perfect coordination is required before maximum results are obtained. Thus the tilting of a lens may cause an astigmatism, or the inclination of the tympanum to a greater or less degree from the vertical, may interfere with the perfect transmission of sound. The result of perfect coordination is observed in the one by the production of marvelous artistic creations, in the other by equally wonderful combinations of sound meeting in harmony. The olfactory in man, like the sense of taste is hardly worth consideration, as its capacity for either transmission or reception is perfunctory.

THE CONTROL.

Emerging from this jumble of complexities surrounding the neural control, we enter the domain of the control itself. So far the reactions of transmitted impulses have been considered, its dependence upon various mechanisms of special sense, and its duty to secure coordination, have been roughly outlined. The possibility and degree of variation, due to the inefficient service of its aids has been mentioned, also its amenability to suggestion. There yet remains the neural control when deprived of its special senses and its driving impulses. Difficult indeed is the conception of this thing as an entity, unless we accept the vague fancies of the ancients and call it a soul.

However, assuming the structure of the body to be zonal in nature, the neural control would of necessity have to be formed from elements donated by each zone, thereby supplying the essentials of coordination and function. A study of the neural control, would however, eliminate all the factors with which it is surrounded, even the zones from which it derived its elements. We would then have a group of elements whose potential would be in direct ratio with their number and ability to function. In this case the consideration of an individual element might lead to an estimate of the potential of the group. Here there intrudes the elusive, intangible factor, attributable to the innate inability of the mind to reason except from simple analogies. To speak of energy, either electronic or atomic, or the principles of chemical attraction or gravitation, would lead to nothing. We accept these principles as axiomatic in their application without understanding. It is useless, therefore, to attempt an analysis of what we term nerve energy, yet we can accept as a fact that such energy depends upon the presence of neural elements. Moreover, the quantitative nature of its energy must follow variation in the quantitative amount of elements. In the matter of qualitative factors we can only surmise. Every neural element may be protean in its potential, or contrarily may differ in functionable adaptability. The fact that special senses are formed, suggest special adaptability, though no reason exists for assuming such an hypothesis to be correct. The optic nerve, if supplied with the mechanism of conduction, may be as well able to transmit auditory impressions, as the aural, or vice versa. The inability of the afferent nerves to transmit efferent impulses

may be only apparent, or it may be that nerves of special sense are formed from elements differing in potential from those of the neural control. However, the phenomena of life, as we observe its manifestations would indicate that neural elements had special adaptability. In either case the phenomena that is of interest is presented by a group of elements capable of forming judgments, and even if a reasonable solution of this problem were available, there would yet remain an unknown potential.

The bewildering possibilities suggested by the appearance of strange and unknown forms of energy such as are manifested in telepathy, mind reading, and thought transference excites the imagination. The existence of an astral body and its possible projection follows as a natural inference. However, if the neural control is a complex, it must receive the factors of its complexity from its elements, in a similar manner to that in which it receives the quantitative factors of its elements from its zones.

The quantitative factors together with the qualitative make up the neural control and while an estimate could possibly be made as to the former, it would be impossible to even approximate the latter, formed, as it is assumed to be, by donations of elements from the body zones, the quantitative factor would resolve itself into a question of the absence or presence of the donations. This would have significance wherein relative variations in size could be observed.

We know that teratomata are produced having headless bodies, and from this fact, could infer that zones can and do proliferate without donating neural elements, but the presence of a head of its size or shape could not be used as a positive index of the quantitative aspect of the neural control. It must not be assumed that the contents of the cranium constitute the neural control. Far from it. The control does not proliferate. It is doubtful that it has growth, as growth would entail the need of supply and waste. Therefore from birth to dissolution it remains as first formed by the grouping of its elements. Exceedingly minute as this entity must be, it should be obvious that its position as control requires a huge complex as an aid, and it is this complex that fills the skull.

It is, of course, probable that a body having donated the required elements to form a perfect neural control, might fail to furnish the normal amount of material to equip the mechanisms of special sense. We would then have a small skull enclosing a very acute intelligence, capable, no doubt, of making up its deficiencies in special aids.

If, however, the control has been formed with a deficiency of elemental donations, it would be improbable that such a control would require the same number of aids as a normal group. If present they would only add to its inability, and if absent would present an index of the deficit in the size of the head.

Therefore a small head attached to a body incapable of coordination, or having obvious mental deficiencies of greater or less degree, would be the index of an imperfect neural control, one which lacked in zonal donations, and which as a conse-

quence, would be unable to function normally, even if equipped with perfect mechanisms of special sense.

As space forbids a lengthy consideration of the subject, it can only be remarked in closing, that the neural control seems to represent a plastic entity whose susceptibility to suggestion is its most astonishing attribute. Its impulses (instincts), its special senses, its environment—one and all sway it from one extreme to another. It gives the impression of seeking an outlet by accepting anything offered, then finding the means or the information to be unavailable or untruthful, it turns to something new. Most of its abnormalities are the result of accepted suggestions leading it to the brink of destruction, hence it doubts everything that is new, or apparently new, yet blunders time after time because of its limited experience.

620 WEST 190TH STREET.

INTESTINAL SYMPTOMS IN MALARIA.

BY CHARLES GREENE CUMSTON, M. D.,
Geneva, Switzerland.

Intestinal morbid phenomena are to be counted among the reactions of malaria, and to these I desire to call attention. Some arise during a malarial paroxysm and have only an ephemeral existence; others are quite independent of any attack and represent individualized stubborn accidents of some duration. To the chronic intestinal accidents of paludism I shall not refer. No matter how frequent or serious they may be, their origin is quite variable and is due either to intestinal or hepatic lesions. The clinical picture is more likely to be that of dyspeptic states rather than true enteritis, although a number of observers, impressed by their diarrheal or mucorrhœic character, are inclined to classify them among the enteritides.

On the other hand, the acute infections are easier to study and present a considerable clinical interest. Their origin is more univocal and their nature quite similar. The acute, temporary and occasionally almost cyclical character makes of them a class by themselves; their early occurrence in malaria defines them distinctly from chronic lesions or from functional or glandular disturbances of long standing which might disfigure their clinical aspect. Finally, their fleeting character facilitates a comparison eminently useful from the physiological viewpoint between the reactions of the paroxysms and those entirely different arising in the premonitory or intercalary state. On the other hand, as they are simply the stepping stone to chronic accidents, they foretell the progressive development by throwing light on the true causes, and permit of a better understanding of the biological processes which govern them.

The intestinal accidents of acute paludism consist essentially of watery diarrheal intestinal discharges. They are for the intestine what bilious vomiting is to the stomach during a paroxysm. They are accompanied by epigastric pain and hepatic tenderness. The liver is increased in size. The intestinal reaction consists of frequently repeated intestinal discharges of a

serous, bilious or mucorrhœic liquid, which causes a burning sensation in the anus. They sometimes last as long as the attack of malaria, but generally subside on the second or third day. They cease with the sudoral crisis.

Abrami and Foix divide these intestinal accidents into two categories, namely diarrhœic and dysenteric, and maintain that the former are more fleeting, while the latter are more stubborn, but in reality, the first indicate an almost physiological excitation of the liver, the latter a true lesion of the intestine, whose progressive development may end in chronic colitis and cachexia. In some cases the diarrhœa appears as much as two hours before the onset of the malarial paroxysm, in others only a half hour or fifteen minutes before, announcing the imminence of the attack. Out of a total of seven cases observed by Loeper, of Paris, three times the diarrhœa disappeared with the chill, three times it continued up to the sudoral phase, and in one only did it continue until the following day. One of these patients later on presented an atypical form even after treatment with quinine and arsenic, exclusively characterized by attacks of diarrhœa with hardly any elevation of the temperature, and accompanied by enlargement of the liver.

These intestinal accidents may, consequently, be very early in their occurrence and, in a way, are a sort of prelude to the paroxysm of malaria. Out of a total of eighty-two patients, Loeper found it thus in nine per cent. and always with the same character. The diarrhœa is never painful, there is no intense colic reaction and palpation of the abdomen is painless. Alone, the enlargement of the liver is constant, contemporary with the diarrhœa and occurring quite as early in the process, indicating the relationship between the hepatic and intestinal reactions. Loeper never found any glairs or blood in the intestinal discharge, and only occasionally a slight mucorrhœa. The stools were invariably very liquid, somewhat frothy, brown, yellow or green in color, but always becoming green when exposed to the air. Therefore, these are bilious stools, similar to polycholic stools accompanying certain hepatic morbid processes or such as occur during certain thermal cures, for example Châtel-Guyon, Grande-Grille or Vihel. For that matter, it is not uncommon to observe a mild icterus and a bilious tint of the urine on the next day. Besides, the blood often contains a rather high content of urea which may reach forty to fifty centigrams to the litre of serum. The serum is distinctly yellower than normal, while the cholemia is higher than ordinary cholemia, and these data suffice to prove, as the clinical examination predicted, the part played by the liver in the various morbid manifestations.

Desirous of more precisely establishing the hepatic origin of certain forms of malarial diarrhœa, Loeper carried out a more complete and close examination of the stools and hepatic functions. The examination first of all dealt with the chemical composition of the stools, their tenor in bile and pigment. After this attention was given to the liver in relation to its functions. Research for biliary pigment in the stools was positive, Schmidt's technic with a three per cent. to five per cent. mercurous

chloride solution caused the characteristic green hue. Cholesterin was also detected and occasionally even the biliary salts. Carbohydrate and muscular débris were noted and merely indicate a rapid transit through the intestine. There was no albumin undoubtedly because no blood or serosity of inflammatory origin was present in the stools. On the other hand, search for amyolytic ferments, according to the technic of Ambard, Binet and Stödel, often placed a large proportion of amyolysis in evidence, a fact which would tend to prove that the pancreas, like the liver, is the seat of an abnormal functional excitation and of an exaggerated secretion.

Exploration of the liver may be carried out by several methods, the one most frequently employed being alimentary glycosuria and the study of the nitrogen coefficient. In respect to the disturbances so far considered and whose principal character is their extreme suddenness and fleeting nature, it is evident that the test of alimentary glycosuria can only be utilized with difficulty. The same may be said of alimentary glycemia, which Beaudoin has tried to substitute for glycosuria in many cases. On the contrary, the nitrogen coefficient can be quickly established by an examination of the urine at the onset of the attack and during the phase of full development. It unquestionably gives interesting results, since it permits one to note from the pre-monitory phase a very high content—from ninety-three to ninety-six centigrams, and in the later phase, especially the terminal, the rather low readings of eighty and seventy-six, which in the first instance show an excitation of the organ, in the latter an inhibition. Another still more certain proof of this hepatic excitation can be found by the study of adrenalinic glycemia. It is a well known fact that an increase of sugar in the blood is a result of an injection of adrenalin. This increase, according to Loeper's researches, is constant and invariably about equal in a healthy individual, submitted to a similar diet. As an echo, there is glycosuria, but glycosuria is less constant than glycemia. The rise of the glycemia is due to exaggeration of the amyolytic power of the liver and as both Verpy and Loeper have surmised, many data can be obtained from its pathological variations relating to this very important function of the gland. Loeper employs the following technic:

The patient should be fasting and in identical former alimentary condition (one litre of milk, mashed potatoes and macaroni). An injection of one milligram of adrenalin is given in the thigh and both before and after the injection a sample of blood is taken and by Bertrand's invariable procedure, the sugar is estimated in the state of glucose. In normal conditions the glycemia increases very quickly and the ascending curve returns to the normal after the lapse of about three hours. The most constant figure is that of the first hour and it is for this reason that Loeper has taken the sample of blood at the end of the hour. In a normal subject the increase of the glycemia attains from forty to fifty centigrams with a most curious regularity. In affections of the liver it is quite variable, much lower than forty centigrams in some, much over forty in

others, even reaching one gram in some cases. Low increases occur in atrophic cirrhosis, in serious morbid processes of the liver and in exhausted hepatic glands and hepatic insufficiency. The high rates occur in livers stimulated by the violent initial reactions of acute diseases and the more durable ones of hypertrophic and hyperplastic hepatitis.

In acute malarial paroxysms these same phenomena of excitation and of deficit are most manifest. At the onset of the attack, at the very time that the diarrhea takes place and the liver prepares its defensive action, the reaction increases and may attain from seventy-five centigrams to one gram eight centigrams. At the height of the attack it constantly diminishes and hardly ever exceeds seven to ten centigrams. Then the sugar content progressively returns to normal. A rather curious thing is that the preceding glycemia is usually more intense at the onset of the attack and less during the phase of full development, but the adrenalin reaction is not greatly disturbed by these initial variations. These variations are often, but not always, absolutely proportional with those of the nitrogen coefficient or that of the alimentary glycemia, because they are related to the different functional processes; in some the ureogenic, in others amyloplexic, in still others amylolytic.

It is curious to observe with what rapidity, the attack having ended, the hepatic reactions return to their previous state. These change later on as successive attacks occur, following the same plan and order, then they lose their importance, their regularity and distinctiveness. This is because in the advanced phase of paludism the test is no longer made on new soil but on one that has been overturned. The hepatic gland gradually becomes accustomed to these multiple irritations and becomes immune to them. The charts are no longer those of frank paludism. The progressive changes of the liver succeed these successive assaults so that the various tests do not give their former distinct results.

The liver is unquestionably, of all the abdominal viscera, the one which gives rise to the most interesting reactions during the evolution of chronic malaria, namely, hypertrophic and nodular hepatitis, resulting from repeated functional excitations, each one of which adds its quota and leaves its imprint on the glandular parenchyma. Or there may be an atrophic hepatitis, the hepatic activity becomes extinct and the secretions progressively dry up. Therefore, to these two orders of lesions correspond two very different functional states which are distinctly revealed by a chemical analysis of the blood and urine. In the first are met the high nitrogen coefficients, marked glyceamic reactions and high percentages of urea; in the second, a lowering of the nitrogen content, a diminution of the glycemia and blood amylolysis, and the adrenalin test increases the glycemia to eighty centigrams to one gram in the first, while in the second it is hardly twenty-five to thirty centigrams.

From these functional hepatic disturbances a series of general and abdominal symptoms result, one of the most frequent being diarrhea. The diarrhea of chronic malaria becomes progressively installed, it then becomes permanent and leads to caehexia. Al-

though its origin may be a superadded dysentery, awakened and kept up by the malaria, or even a true malarial inflammatory mucorrhoeic enteritis, in the stools of which some observers have found red blood cells containing the plasmodium, it is quite as often due to some morbid change in the liver. It is no longer an enteritic diarrhea but a dyspeptic one, in which an excess of bile or hepatic insufficiency are to be held responsible, and should the enteritic process develop later, it has none the less been set up by the dyspeptic state. Thus the variations in the hepatic functions during an acute paroxysm of malaria, in their almost cyclical and rapid succession, sum up the changes of these same functions in the evolution of the malarial liver. They are, to a certain extent, the imprint that the malarial process makes on the entire existence of the patient. In what has been said I have endeavored to make clear the understanding of the intestinal accidents of paludism in general, and this now brings up the subject of hepatic dyspepsia.

Some of these intestinal reactions might well be given the name of premonitory diarrheas. Exact from the clinical viewpoint, in the sense that the diarrhea announces the near advent of a paroxysm, the term premonitory is inexact from the standpoint of physiology, because the diarrhoeic reaction is not, in the strict sense, a humoral reaction. It is, in some cases, the indicative reaction, while other symptoms, such as lassitude, chilliness and discomfort, pass by unnoticed. It marks the entrance upon the scene of the parasite that an examination of the blood from the liver, spleen or even of the general circulation will reveal. This has been done by obtaining blood simultaneously from the liver by puncture and from the pulp of the finger. In two cases the plasmodium was the falciparum type, in the third case it was the vivax. On the slides the crescent shaped extraglobular bodies were seen adherent on the red cells, young schizonts with their annular shape and fine nutritive vesicle and even some rose shaped ones. Staining showed these details distinctly. They were the parasites of the tertian, usually simple, rarely those of pernicious paroxysms. Unquestionably, the fact that they were found does not necessarily imply that the diarrhea would not have occurred without them.

This early appearance of the diarrhea testifies to an invasion of the liver by the parasite and likewise indicates the exciting action of the latter on the hepatic gland and the effort of the liver to rid itself of them by the bile. It is quite natural that it may precede the initial chill since, on its way, it is the liver that the parasite encounters before becoming scattered in the general circulation.

It is difficult to say why in some patients the hepatic reaction is more prone to occur than in others and there is no evidence that there is an abnormal susceptibility of the organ. It appears probable that, although not yet verified, the intimate mechanism of the excitation is the outcome of a direct action or the secretion of toxic substances, perhaps even the production of new proteic bodies, as has been advanced by Abrami who has attempted to explain the production of the paroxysms by this theory.

LONDON LETTER.

*(From our own Correspondent.)**First Annual Report of the Ministry of Health—St. Andrew's Institute for Clinical Research—Report of the Interdepartmental Committee on Insurance Records—The Municipal Hospital at Bradford.*

LONDON, September 17, 1920.

Two reports notable from the viewpoint of public health and preventive medicine have recently been issued, the most important of which is the first annual report of the Ministry of Health. This document begins by discussing the work done by the Ministry in fighting tuberculosis. The main conclusions of a report of an Interdepartmental committee appointed in 1919 to investigate the matter were that the existing accommodation in sanatoria and hospitals for the treatment of tuberculosis in the United Kingdom was, as a result of the financial and other restrictions of building during the war, most seriously inadequate in quantity; and that in the development of schemes for the institutional treatment of tuberculosis it was necessary not merely to increase the available sanatorium and hospital accommodation but in addition to secure the provision of facilities for the occupational and vocational training of sanatorium patients and also for their permanent settlement, after training, in village communities where they could earn a livelihood under sheltered conditions. The sanatorium patient would thus pass through three stages, first of treatment in the sanatorium, second of training under medical supervision in the training colony, and third of permanent employment or occupation in the village settlement. The training colony, though it might be physically separate from the sanatorium, should always form part or be a direct extension of the sanatorium. The committee also expressed the view that the tentative standard of one sanatorium bed and one hospital bed for each 5,000 of the population, which was suggested in 1912 by the Departmental Committee on Tuberculosis, had now proved to be insufficient.

It was also recommended by the Interdepartmental Committee, with regard to sanatoria for soldiers, that the national scheme for the treatment of tuberculosis should be supplemented by a scheme for training and employment in training colleges and village settlements, which would in the first instance be available for tuberculous ex-service men. The Treasury has approved the scheme and the funds will be supplied. It is pointed out that the selection of suitable occupations in which tuberculous men should be trained while under treatment at sanatoria has been receiving consideration for some time past. The difficulties which will arise in the absorption of these men into industries are considerable, and probably the only method by which many of the men will be able, after training, to earn a livelihood for any prolonged period without frequent relapse and ultimate permanent breakdown is by being placed in such special conditions and surroundings as will afford them shelter from the full stress of competitive industry by enabling them to live in a village settlement or an industrial colony established on lines specially designed for these purposes. It is essential to remember in this

connection that the working capacity of the tuberculous person in whom the disease has developed to any appreciable extent is seriously impaired, perhaps permanently. The Ministry is accordingly in communication with the Treasury on the whole question of village settlements and other kindred arrangements under which the tuberculous patient would, after training, be able to be employed under specially sheltered and favorable conditions.

A considerable part of the report of the Ministry of Health is taken up with a consideration and discussion of the venereal problem and in giving an account of the means taken by the Ministry for preventing and treating the disease. During the year 1919 the total number of patients dealt with for venereal disease for the first time amounted to over 98,000; of this total 15,500 had been proved on examination not to be suffering from venereal disease, a figure which seems to indicate that persons who are apprehensive that they may have contracted venereal disease are willing to avail themselves of the facilities provided for diagnosis and treatment. The attendance at the treatment centres during 1919 amounted to 1,003,000, as compared with 485,000 in 1918. The number of treatment centres open on December 31, 1918, was 134 as compared with 160 on December 31, 1919, but the increase in the facilities available was much greater than is indicated by these figures owing to a considerable increase in the number of clinics held each week. The work of the National Council for Combating Venereal Disease is favorably commented upon and it was agreed that a publicity campaign should be conducted by the agency of this body. The National Council submitted a program of special propaganda and publicity work estimated to cost £30,000 (\$150,000). The estimate was carefully scrutinized by the Ministry, and the sanction of the Treasury was obtained to a grant of not exceeding £20,000 (\$100,000) in respect of press advertisements, propaganda by cinema films, slides, and exhibits, by pamphlets, posters, and other literature and in respect of special propaganda in backward areas. During the year ended March 31, 1920, the Ministry paid grants in aid of venereal disease schemes amounting to £224,716 (\$1,123,580).

With regard to maternity homes and hospitals, the report states that institutional accommodation for confinements has in the past been provided in general maternity hospitals supported by voluntary subscriptions and in lying-in wards in infirmaries and workhouses provided by Boards of Guardians. The number of beds for maternity cases in general hospitals is difficult to estimate approximately, since in many instances no special accommodation is reserved for such cases. They are chiefly for complications of confinement, but a certain number of normal cases are also taken in hospitals which train medical students and pupil midwives. The number of maternity hospitals, according to the hospital return of 1915 issued by the Local Government Board, was eighteen, with about 560 beds. Nearly all Boards of Guardians have some institutional provision for maternity, either in the wards of the workhouse or in a separate infirmary. The Town

Council of Bradford was the first local authority to establish a municipal maternity hospital. This was in 1915, and since that date forty-five maternity houses and hospitals have been started, the majority by local authorities and the remainder by voluntary bodies working in cooperation with local authorities carrying out maternity and child welfare schemes. The accommodation which is provided in adapted houses comprises altogether about 500 beds. Apart from this, 300 beds for confinements exist in homes for unmarried mothers and their babies, although the general rule in these institutions is for the women to go to a lying-in hospital for her confinement, returning to the home afterwards. The policy of the Ministry has been to encourage local authorities as much as possible to provide accommodation for maternity cases. The shortage of houses and consequent overcrowding have emphasized the need for homes for normal confinements as well as for hospitals for complicated cases. The difficulty of building has rendered it necessary in most cases for an existing house to be adapted for the purpose, and suitable houses have been hard to obtain. Nevertheless proposals for about thirty-five additional maternity homes have been sanctioned or are now under the consideration of local authorities and of the Ministry.

As for children's hospitals, the report points out that the accommodation for the treatment of children under five in general and special hospitals supported by voluntary contributions has been supplemented in the course of the development of maternity and child welfare schemes in various ways. In maternity and child welfare centres which receive a large number of children the medical officer examines those who for some cause which is not immediately apparent are not making satisfactory progress. About twelve centres have provided observation beds in which these children can be kept until the reason why they are not thriving is ascertained, and a remedy for their condition can be applied. Such observation beds tend to develop into wards or small hospitals for ailing babies, and in sixteen other instances new infants' and children's hospitals have been established, frequently in connection with centres for children under five suffering from marasmus, rickets, and similar conditions not ordinarily admitted to general or children's hospitals. Hospitals for general diseases and illnesses for children under five have been established in five districts in which the hospital accommodation for children was inadequate, and more institutes for all of these classes are now being planned or considered. A hospital for cases of ophthalmia neonatorum has been provided by the Metropolitan Asylums Board. Altogether about 220 beds have been added to the hospital accommodation for children in connection with maternity and child welfare schemes.

Attention is drawn in the report to the fact that the passing of the Nurses Registration Act, in December, 1919, ended a controversy which had lasted some twenty years. The Act provides for the establishment of a General Nursing Council, two thirds of whose members should be nurses, the

remaining one-third being representatives of the departments concerned, of the medical profession and of the nurses' training schools. The first council is wholly nominated, but the act provides that in from two to three years' time when a sufficient number of nurses have been registered to form an adequate electorate, the nurse members of the second and all subsequent councils shall be elected by the nurses on the register. In accordance with the invaluable practice in establishing registers of this kind, the interests of existing nurses are fully safeguarded, and those engaged in bona fide practice as nurses for at least three years before November 1, 1919, may be admitted to the register without examination, provided that they apply for registration within two years after the date when the rules to be made by the General Nursing Council come into operation. Subsequent admissions to the register will be made only by examination after the prescribed training in an institute approved by the Council. Similar measures were passed establishing nursing councils in Scotland and Ireland, and provision is made in all three acts for reciprocal recognition by the various councils of nurses registered in other parts of the United Kingdom.

* * *

The other document which has just been issued is a report of the interdepartmental committee in relation to certain phases of national health insurance and is chiefly valuable by reason of its appendix, which is a memorandum on some of the medical aspects of the National Health Insurance Act by Sir James Mackenzie and the staff of the St. Andrew's Institute for Clinical Research. As mentioned in a previous letter Sir James Mackenzie, the great heart specialist who is known well by the medical profession of America, became convinced that much disease could be prevented from attaining serious proportions if the general medical practitioner was cognizant of some of the early symptoms of disease and was able by proper treatment to prevent these early manifestations from going further. As the general practitioner is the only medical man who has an opportunity to observe and study these early symptoms Sir James suggested that these, and especially the panel practitioners, should be taught how to detect such symptoms and treat them properly. Sir James not only suggested such a scheme but gave up his practice in London and founded the St. Andrew's Institute of Clinical Research in St. Andrew's, Scotland, for the purpose of carrying his views into effect. It is pointed out in the memorandum that though the vast majority of medical students become general practitioners no attempt is made to teach them how to make use of their opportunities in general practice and no hint is ever given them that the phases of disease which they will meet will be different than those they have seen in the hospitals. Consequently there is an urgent need for a definite course of training students in their last year as to how they should conduct their practices as panel doctors. If there was a scheme by which they could learn how to question a patient intelligently, how to make short but accurate

notes, how to watch the patient as he passes from one phase of disease to another, the working of the Insurance Act would year by year be greatly facilitated, while a great impetus would be given to the investigation of those dark fields of medicine which only the general practitioner can explore.

The memorandum goes on to point out that the system of specialization at present prevalent enables the specialist only to see disease at a late stage. Moreover, as in ill health there are reactions affecting several organs or systems, a man who restricts himself to the study of but one organ or system cannot acquire the power of detecting the primary cause of the patient's ill health. It is recognized that a general practitioner who makes a special study of the diseases of one organ or system is better qualified in that he has a wider experience and can therefore take a broader outlook of his patient's complaint, besides having an opportunity for seeing disease at an early stage. The following are the methods pursued at St. Andrew's Institute. 1. Each clinician has a private room in the institute. This is reserved from eleven to one on Mondays, Wednesdays, and Thursdays for research cases. During the rest of the day each practitioner may use his private room as a private consulting room. An index file and cards are provided in each room upon which brief notes are kept of each private or panel patient. These cards will, in time, form records of the life history of each patient. In the event of a patient removing to another district these notes can be sent to his new attendant. 2. Cases for research are selected from his own practice by each member of the clinical staff. These are first seen by him and he is at liberty to consult Sir James Mackenzie or any colleague at any stage of the case. If any special investigations are required, these are carried out by the staff of the special departments. 3. On Tuesday afternoons some special subject, arranged beforehand, is discussed by a general meeting of all members of the staff. 4. On Friday afternoons the whole staff discuss the cases seen during the week and any suggestions for investigation of any case made at that meeting are proceeded with and added to the record.

* * *

In an article on the Municipalization of Hospitals, published recently in the *British Medical Journal*, Dr. Charles Buttar describes the Municipal hospital in Bradford, emphasizing the importance of a study by the medical profession of the methods by which this institution was brought into existence and the proposals for its management.

Dr. Buttar goes on to say that for a long time there were no medical men in the city who confined themselves to purely consulting and specialist work and that, more than ten years ago, it was recognized that the buildings of the Royal Infirmary, where much of the institutional work was done, were out of date and insufficient, and a site for a new infirmary was acquired. But the £200,000 then thought necessary was never collected and the war interfered with the proposals for building. It appears probable that the project of the Bradford Municipal Hospital is to be legitimized by a clause in the

Ministry of Health bill. A site has been leased where there will be as little overcrowding of buildings, and as much open space as possible. This new hospital is expected to have 1,148 beds in ten pavilions; the medical ward to accommodate 502, and the surgical, 324 patients. To maternity cases 90 beds will be allotted, to children 84 and to infants 40. The remaining 108 are for venereal cases.

In order to build up the hospital on modern lines, it is proposed that the institution should consist of a number of small units, each composed of senior part time officer, physician or surgeon, an assistant (part time) and a resident officer. The City Council, which is responsible for the management, will delegate the care of the hospital to the Public Health Committee. The medical staff will consist of part time senior and assistant medical, surgical, and gynecological officers, and of the residents attached to the units. It is proposed that the senior officers shall be consultants or specialists employed for two hours each on four days a week. The remuneration suggested for this service is £500 a year. The assistant medical officers may be general practitioners, who would be employed for six hours a week, and be paid £300 a year. The residents will be whole time officers, and no suggestion seems to have been made as to the rate of remuneration to be paid them. Patients will be admitted through the outpatient department, which is to be open, apparently, to any inhabitant of Bradford, but which it is hoped will be fed from the various clinics, the outdoor Poor Law medical officers, and by general practitioners. No mention is made of emergency operations, which often occur in the night.

One interesting proposal in connection with carrying out the plan of the hospital is the matter of the senior medical officer. He is supposed to have a university degree or to be a Fellow of one of the Royal Colleges, and not to be in general practice, nor hold any other hospital appointment save with the consent of the committee. Now the committee proposes to purchase eight hours a week of a consultant's time, and it is a little difficult to see why they should be anxious to know what he does with the remainder of his time. May it not be that this provision may deprive them of the services of some of the more distinguished consultants?

The attitude of the population of Bradford toward municipal health enterprise is interesting. Some doctors assert that their practice among children has almost ceased. One doctor regarded Bradford as so municipalized that the City Council takes charge of the whole population "from conception to cremation."

It is proposed that charges shall be made to patients, according to the means of each, but no special amenities will be provided for those who pay the larger sums. All will be treated and fed in the same way.

Though the plan outlined above is interesting, the question is asked, why should attempts be made to fetter part time medical officers? Would it not be well for the Minister of Health to withhold approval of a scheme embodying such principles as these in Bradford until some measure of consultation with the medical profession has been achieved?

NEW YORK, SATURDAY, OCTOBER 23, 1920.

ACUTE ADENOIDITIS IN CHILDREN.

This affection is of great practical importance. In infants and children up to the age of five years it occurs as frequently as it is overlooked. Usually these small patients are treated for almost every disease excepting the right one and in most instances the specialist is finally consulted for the complications. In practice, all that is necessary is to recall that there is such a disease as acute adenoiditis for the purpose of recognizing it, because its symptomatology is very special and really characteristic. The affection is especially frequent in winter and at the beginning of spring and autumn. In an infant or young child after coryza, a temperature develops; the baby becomes restless, sleeps poorly, snores and breathes with the mouth open. At the same time a paroxysmal and almost incessant cough develops of a type much like that of pertussis, allowing the patient little rest. The cough, usually dry unless there is a concomitant tracheitis, occasionally precedes in somewhat long paroxysms during the day but is much more accentuated at night when the child is lying down. It is not uncommon to find a temperature of 102° to 104° F. lasting for several days. Generally it lasts for five or six days, sometimes a fortnight or even a month. Even when long continued the child is likely to retain its appetite and eat as usual.

An examination of the throat will enlighten the diagnosis. The pharynx and tonsils are bright red and if the velum is pushed up a transverse line of accumulated mucus will be perceived at the upper

part of the cavum. This band of mucus varies in thickness and has a mucopurulent look. If the finger explores the parts adenoid growths will be detected immediately. The long duration of the process in some cases, the temperature and the difficulty in feeding may result in a certain degree of emaciation and change in the general health. On the other hand, complications of various kinds may arise such as bronchitis, bronchopneumonia, otitis, asthma, and laryngitis stridulosa.

Two types of the process deserve mention; a dry form with paroxysmal coughing, without secretion, and a catarrhal form with secretions and rise in temperature but without cough. The diagnosis is easy if the physician will only recall that acute adenoiditis is relatively common in young subjects, especially when the patient offers the characteristic facies of adenoid growths, and in infants when they sleep with open mouth and snore.

Auscultation will immediately eliminate bronchitis or bronchopneumonia. In simple acute tracheitis there are no nasopharyngeal symptoms, while tracheobronchial adenopathy can be also eliminated by the absence of presternal or interscapular dullness or subdullness. In whooping cough the paroxysms of cough are not so frequent, the affection is apyretic unless complications arise, and viscous mucus will be discharged with the coughing. Adenoiditis is prone to frequent recurrences and removal of the growths should be undertaken as soon as the inflammatory phenomena have subsided. In the infant, the treatment consists in disinfection of the cavum by morning and evening instillation of thirty centigrams of resorcin in twelve cubic centigrams of sterilized oil. In older children gomenol oil or solutions of protargol or collargol may be used, as well as irrigations with tepid water for removal of the secretions. The bromide salts are useless for controlling the cough and urethane is used in the daily dose of from twenty-five to fifty centigrams after the age of one year.

FRENCH RESEARCH ON GAS GANGRENE.

When gas gangrene appeared among the troops on the Western Front little was known of this serious complication of wounds. The condition had almost disappeared from peace time practice and the present medical generation had practically forgotten it. French medical men determined to learn all that was possible concerning it, so as to be able to treat it effectively. According to Dr. E. Sacquépée, professor at the Val-de-Grace, Paris, writing in the

French Supplement of the *Lancet*, September 18, 1920, these efforts have been directed above all to elucidate the pathogeny of the accidents. The complication was of an infectious nature and it was necessary to find out the species of microbe responsible for it.

Before the war knowledge of the pathogeny was as follows: Pasteur following Davaine in his study of experimental septicemia showed that the infection was due to the *Vibrion septique*. Chauveau and Arloing then demonstrated that this same germ also existed in gas gangrene in human beings. Clinical researches into the question then became difficult in France, since the first effect of the application of Pasteur's principles to surgery was to render gas gangrene extremely rare. On the other hand in foreign countries, especially in Germany and America, the study of certain new facts was possible. Welch and Fraenkel, and following them a number of other observers, charge Welch's bacillus, the *Bacillus perfringens* of French writers, with being the main cause of the condition. According to these authorities the *Vibrion septique* seems entirely eliminated as far as its influence goes.

The war gave opportunities for further investigations under favorable circumstances of which full advantage was taken. Welch's bacillus was found to be the predominant microbe implicated. The first work of the French investigation began in May and June, 1915, and was based on the following principle, i. e., that the best criterion of a pathogenic species is constituted by its ability to reproduce the malady experimentally. It was found that Welch's bacillus could reproduce the local lesions of the gangrene, but it could not be made to produce a potent toxin.

The investigators therefore thought that an examination should be made to determine whether there were not in the gangrenous tissues other pathogenic germs which comply better with the experimental criterion. In the majority of cases investigations in this direction gave an affirmative answer. They found either the *Vibrion septique* or a new bacillus which was later to receive the name of *Bacillus bellonensis*. In short, it was made clear that gas gangrene was associated with three species of organisms, Welch's bacillus, *Vibrion septique* and *Bacillus bellonensis* and the Inter-Allied Surgical Conference, which met at Paris, came to the same conclusion.

The results of the analysis of 121 cases under the French investigators' personal supervision were: Welch's bacillus, eighty-two per cent.; typical *Vibrion septique*, twenty-eight per cent.; nontypical *Vibrion septique*, eleven per cent.; *Bacillus bellon-*

ensis, thirty-five per cent. The germs were often associated in pairs. An analytical study of the *Bacillus bellonensis* showed that it is a highly pathogenic, very toxic species, capable of reproducing perfect gas gangrene experimentally. As for specific treatment, a knowledge of the causative germs, suggested the application of a specific serotherapy either against all three germs or against the germ involved in each particular case. The carrying out of this conception resulted in the preparation of three serums. The really great difficulty was to know which serum was to be used in each case. In most of the cases it was decided to inject all three simultaneously, although this was evidently only a makeshift procedure. Even so this method has given decided results. However, in the last months of the war a means of rapid pathogenic diagnosis was discovered, so that treatment can now be applied promptly on the right lines. Of course, from the preventive viewpoint this method of treatment is still more powerful, as Sacquépée points out, as it reduces the cases of gas gangrene to a small number of those wounds which are most exposed to it. French investigators clearly defined the pathogeny of gas gangrene and have employed serotherapy, curative, remedial, and preventive, with the happiest results, a really notable achievement.

PHYSICIAN-AUTHORS: DR. FRANCIS
BRETT YOUNG.

Dr. Francis Brett Young, the English poet and novelist, admits that when his father sent him to the University of Birmingham to study medicine he rebelled, for he was already afflicted with that seemingly incurable disease, *cacoethes scribendi*. "But I know now," he declares, "that there is nothing in the world that so fits a man of letters to wrestle with the mind of a man as an intimate acquaintance with his body. Literally and figuratively the doctor sees thousands of men and women naked; he sees the spring of curious motives, he shares strange secrets. A man or a woman will tell lies or feign emotions to the pastor or the lawyer; with the physicians they know that only the truth will help them. There is no education in humanity that compares with the doctor's life; and indeed, the names of great literary artists confirm this."

Unless he has given it up quite recently, Dr. Young is still practising medicine while at the same time writing novels. He took his degree in 1906 and immediately set out to see the world as a ship's surgeon, an easy berth which gave him plenty of leisure to gather impressions and put them on paper. In this capacity he saw the whole of the East, from Egypt to Korea and Japan and then settled
